Outer diameter of fuel rods, mm	9.5
Number of control rods	89
Absorber material	Ag-80, In-15, Cd-5
Drive mechanism	magnetic jack
Positioning rate (10×75 or 750 mm/min), steps/min	75
Primary containment	
Type	prestressed concrete
Overall form	cylindrical
Dimensions (diameter), m	48
Free volume, m^3	90000
Design pressure	
(DBEs), kPa	~650
(severe accident situation), kPa	~650
Design leakage rate, vol % d^{-1}	< 1
Is secondary containment provided?	yes, reinforced concrete (APC protection)

3.1.2. Boiling-Water Reactors

An experimental atomic power plant marked the beginning of nuclear power plant development in Germany. More than 25 years of valuable experience for the further development of the BWR were gained with this 16-MW_e experimental plant at Kahl for which planning started in 1958 and which was decommissioned in 1985. The same applies to the subsequent demonstration plants Gundremmingen A rated at 250 MW_e (1962 – 1980) and Lingen rated at 267 MW_e (1964 – 1977). These two plants, which also

made valuable contributions, have since been decommissioned. As the operating experience gained with subsequent boiling-water reactors of larger capacities and operated exclusively for commercial power production continued to grow, these demonstration plants became dispensable because both power plants (Gundremmingen A and Lingen) were found to require highly capital-intensive backfitting measures to improve their safety.

These demonstration plants were followed by the boiling-water reactors belonging to the 1969 Product Line which were rated at ca. 700 – 900 MW_e (Würgassen, Brunsbüttel, Philippsburg 1, and Isar 1 Nuclear Power Stations). These, in turn, were succeeded by the 1972 Product Line. The present stage reached in the evolution of the German BWR is characterized by the large- capacity ratings of the 1972 Product Line plants – approximately 1300 MW_e (Krümmel, and Gundremmingen B and C).

On December 31, 1988, there were 87 boiling water reactors in operation worldwide and 14 under construction. Table 17 shows the status of BWR plants in Germany in 1989. Table 18 illustrates various evolutionary stages by giving characteristic data for typical BWR plants. An overview of BWR plants operating in different countries is given in Table 19.

The following description of the BWR concept is based on Gundremmingen Nuclear Power Station. The principal technical data for a plant of this type are presented in Table 20.

∗ RPV = reactor pressure vessel.

3.1.2.1. Design

The generation of energy in the boiling-water reactor occurs in the reactor pressure vessel at a lower pressure and lower temperature (7.06 MPa, 286 °C) than in the PWR. In contrast to the PWR, steam for driving the turbine is

generated directly inside the RPV. The heat flow diagram of the steam, condensate, and feedwater cycle is shown in Figure 33.

In the BWR (see Fig. 34), heat released by the fission process is used to boil demineralized water inside the RPV (a) at a system pressure of 7.06 MPa. This water enters the core (b) in a slightly subcooled state (215 °C), is heated to boiling temperature, and partially evaporates. The steam – water mixture produced in the core area passes through the centrifugal-type steam separators (d) located above the core where most of the water is removed. The water is returned to the bottom of the RPV and the steam is routed upward to the steam dryers (e). The main steam for the turbine exits the RPV through four main steam nozzles in the RPV wall and flows directly to the turbine.

The steam exhausted from the turbine is condensed, and this condensate is cleaned, deaerated, and heated before being returned as feedwater to the core via feedwater nozzles (h) on the reactor pressure vessel located above the core (b). A sparger ensures uniform mixing of the feedwater around the reactor vessel with the water flow from the steam separators. The slightly subcooled water is routed downward past the core through the downcomer annulus between the RPV wall and the core shroud; it flows along the bottom of the RPV toward the center and then upward again in the direction of the core.

Boiling-water reactors with the power densities that are common today require forced circulation of the coolant. In early reactors with forced circulation, water from the downcomer annulus was taken outside the RPV to external recirculation pumps that returned the water at an increased pressure to the bottom of the vessel. In the United States, another type of coolant recirculation pumping system was then introduced, in which a system of jet pumps is installed in the downcomer annulus of the RPV and only a small amount of water is recirculated externally to provide the driving flow for the jet pumps. In the reactor pressure vessel shown in Figure 34, several axial-flow recirculation pumps (k) are installed directly inside the annulus to provide internal forced circulation of the reactor water.

Reactor Core. The steam is produced in the reactor core, which is located in the bottom half of the reactor pressure vessel (see Fig. 34). The reactor core is composed of cells, each of which consists of four fuel assemblies and one cruciform control rod (see Fig. 35). Two grids, one located at the top and one at the bottom of the core, hold the fuel assemblies in a lattice configuration. The fuel assemblies are supported directly at the bottom of the reactor pressure vessel by the control rod guide tubes. Orifices at the top of the control rod guide tubes ensure proper coolant flow distribution to each fuel assembly. The reactor core is contained within the cylindrical core shroud, which supports the two core grids and the steam separators located on top. Table 20 contains the main technical data for a reactor core. For economic reasons, a high rate of energy extraction from the nuclear fuel is required. The average discharge burnup serves as a measure of this energy extraction. At modern plants, this value is about 28 000 MW · d/t of uranium, which corresponds to an average operating period of 4 years.

Fuel Assemblies. Each fuel assembly consists of fuel rods arranged in a 6×6, 7×7, or 8×8 array (see Fig. 35). The fuel rods consist of thin-walled Zircaloy cladding tubes, which are sealed gastight at both ends, have an outside diameter of 12 – 14 mm and a length of ca. 4 m, and contain the nuclear fuel in the form of pellets stacked over a length of about 3.7 m. Burnup of the fuel is optimized by using ^{235}U enrichments between 0.7 and 3.9 %. Upper and lower tie plates, through which the coolant passes, hold the fuel rods together to form fuel assemblies.

Spacers provided at several axial locations maintain the desired distance between fuel rods. A central rod holds the spacers in position at different levels. A channel made of Zircaloy encloses each fuel assembly. The functions of the fuel channel are to channel the steam – water mixture produced in the reactor core and to guide the cruciform control rods when they are moved. The control rods are responsible for reactor control and shutdown. They absorb the excess reactivity in neutron-absorbing boron carbide (B_4C), which is enclosed in steel tubes in the control rods (see Fig. 35). The excess reactivity of the initial core is absorbed by gadolinium, a burnable neutron absorber, which is added to the fuel for this purpose.

Figure 33. Heat flow diagram

Components of the Reactor Coolant System. In today's boiling-water reactors, the *reactor pressure vessel* encloses all the components required for the generation of steam (i.e., in addition to the reactor core, the steam separators and dryers, as well as the internal recirculation pumps; see Fig. 34). For refueling purposes, the RPV is opened by removing the head. All external piping connections are welded.

A low-alloy, fine-grained steel that is easily workable is an optimum material for use in light-water reactors. Irradiation has only a small effect on its toughness because of the large water gap between the reactor core and the RPV wall, resulting in a service life of more than 40 years. The wall of the reactor pressure vessel is clad on the inside (see Table 20 for main dimensions and design data). Stringent quality controls during manufacture rule out unacceptable material defects. In-service inspections (by the ultrasonic method) are performed to monitor material conditions at specified intervals during the reactor service life.

A *control rod drive mechanism* (CRDM) (see Fig. 34, g) is provided for each control rod. The drive inserts and withdraws the control rod either slowly by electromechanical means or quickly (by means of a hydraulic system) to scram the reactor. The CRDMs are located below the RPV in control rod drive housings that are welded to the reactor bottom head.

Axial-flow pumps located inside the reactor pressure vessel are used as *recirculation pumps* (r) in the reactor (see Fig. 34). Depending on the capacity rating of the reactor, between four and eight pumps are installed in the downcomer annulus. The pump shaft is led downward out of the RPV through a small pump nozzle in the RPV bottom head and is driven by an external variable-speed electric motor. As in a reactor with natural circulation, the entire volume of recirculating water remains inside the reactor.

The *steam separator assembly* comprises individual centrifugal separators. Here, the steam–water mixture that exits the core area is separated into water, which is returned to the downcomer annulus, and low-moisture steam, which flows upward to enter the steam dryer assembly. There, the steam is dried to a residual moisture content of < 0.2 % in accordance with the design of the saturated-steam turbine.

Reactor Building. The reactor building (see Fig. 36) accommodates the systems and components required for reactor operation; protects the plant against natural or man-made external hazards; acts as a final containment barrier to prevent the uncontrolled release of radioactive materials; and protects the environment against nuclear radiation. The building is a cylindrical structure approximately 50 m in diameter and 70 m in height with a wall thickness of approximately 2 m. The cylindrical primary containment with the pressure suppression system is arranged concentrically inside the reactor building. The space between the reactor building wall and the primary containment–the annulus–

houses the scram system, the residual heat removal, and the nuclear component closed cooling water systems. The reactor well, the fuel pool, and the dryer and separator storage pool are located above the containment.

The *primary containment* is another protective barrier. It is a prestressed concrete structure with a steel lining. The nuclear steam supply system (the RPV, the main steam and feedwater piping up to the first isolation valves, the safety-relief valves, the recirculation pumps, and the CRDMs) is accommodated inside the containment, which is subdivided into the dry well and the wet well. In the event of accidents with or without loss of coolant occurring inside the primary containment, the pressure suppression system serves as a heat sink by condensing the steam in the pool of cold water. A cooling system connected to the pressure supression system provides for heat removal. The pressure suppression system keeps accident pressures to a low level.

Figure 37. Boiling-water reactor safety-related systems

More recent safety scenarios have also considered core melt accidents. To guarantee that the functional integrity of the containment is maintained, it is either inerted with nitrogen or equipped with hydrogen igniters (which ensure timely combustion of any hydrogen released) and provided with an additional venting system for depressurization.

The entire reactor building belongs to the controlled access area. During operation, access is available through airlocks. The containment, however, is normally entered only during an outage when the reactor has been shut down. A slight subatmospheric pressure is maintained at all times inside the containment, and the exhaust air is routed via off-gas filters to the vent stack. All primary system piping that penetrates the containment is provided with two isolation valves.

Reactor Auxiliary and Service Systems. The main safety-related facilities are shown in Figure 37, and the auxiliary and service systems in Figure 38.

The function of the *reactor scram system* is to bring the reactor to a subcritical condition from any state of operation within a few seconds, in the event of accident. This is effected by inserting the neutron-absorbing control rods. Apart from the scram system, a *standby liquid control system* is provided that can be used to shut down the reactor and maintain it in a subcritical condition if the control rod system is inoperable. This system pumps an aqueous solution of boric acid into the reactor pressure vessel.

In the event of an accident, the *residual heat removal system* ensures that the core is adequately covered with water and that decay heat is removed from the reactor after it has been

Figure 38. Boiling-water reactor auxiliary and service systems

shut down. This system can function in both the high-pressure and the low-pressure range, and is of multiple redundant design. During normal plant operation, this system is used (1) to cool the fuel pool when the complete core has been discharged and (2) to cool the water in the wet well. It also performs certain cooling functions during start-up and shutdown of the plant.

In the *reactor water cleanup system*, a portion of the reactor water flow is continuously purified to reduce the content of soluble and insoluble corrosion products as well as any fission products.

Liquid and solid waste processing facilities are provided to treat liquid and solid radioactive process waste (leakage water, resin and filter backwash water, and water used for decontamination work). Depending on the type of wastewater involved, processing is based on solids filtration, mixed-bed ion exchange, or evaporation. A *gaseous waste processing system* is required for the processing and controlled release of gaseous radioactive wastes. The off-gas system is also connected to the turbine and to the plant heating, ventilating, and air conditioning systems.

3.1.2.2. Instrumentation and Control

The instrumentation and control systems are characterized as follows:

Figure 39. Design of boiling-water reactor safety instrumentation and control
RESA = reactor scram; DDA = containment isolation (closure of double isolation valves); LPRM system = local power range monitoring system

1) Subdivision into functional groups with a redundant, decentralized arrangement, and hierarchical structures
2) Clear separation of protective, monitoring, and control functions
3) Prevention of accident situations by means of equipment and measures based on a multilevel concept of response to prevent unnecessary initiation of a reactor scram and other accident-related safety measures
4) High degree of automation
5) Standardization of signal processing levels and control levels

The instrumentation and control systems are subdivided into safety I & C for the reactor, turbine I & C for the turbine generator set, and non-safety-related process I & C.

Safety Instrumentation and Control. Safety I & C (Fig. 39) consists of electrical and electronic equipment necessary to guarantee safe reactor operation. It includes the instrumentation, process monitoring systems, closed-loop control facilities, reactor protection system, and core monitoring systems. All relevant process variables are measured. The measured signals are processed in transducer compartments that are physically separated from each other.

Reactor Control. The control rods and reactor water recirculation pumps represent the elements for reactor power level control. In control rod control, neutrons are absorbed by the boron carbide contained in the blades of the control rods. In this process, the further the control rods are inserted into the reactor core, the more thermal neutrons are absorbed (causing a power reduction). Conversely, the more the control rods are withdrawn from the reactor core, the fewer thermal neutrons are absorbed (causing a power increase).

Recirculation flow control influences the volume of steam in the reactor core and hence the moderating capability of the coolant. If flow through the core is slowed down by reducing the speed of the recirculation pumps, the steam voids remain longer inside the core, curtail the moderating effect of the water, and hence reduce the power level. If the recirculating water flow is increased, the moderating effect is increased as is the power level.

Two different operating modes are possible (Fig. 40), depending on the intended service of the plant [(1) based-load operation with scheduled load changes or (2) peaking service with unexpected load changes from the partial load range]:

1) Adjustment of the reactor power level by using the control rods with the recirculation pumps operating at minimum speed (Fig. 40, line i) until the 100 % flow control line (line c) is reached (at ca. 60 % reactor power). Above this value, power is adjusted through regulation of the recirculation pump speed.
2) Adjustment of the power level by using the control rods up to approximately 40 % power (line i) and beyond that by using both the control rods and the recirculation pumps in such a manner that the pump speed is maintained constant at about the center of the speed band to enable optimum accommodation of rapid load changes (lines f and e).

Figure 40. Control of boiling-water reactor by control rod adjustment and recirculation flow control
a) Variable neutron-flux scram limit; b) Variable rod block limit; c) 100 % flow control line; d) 80 % flow control line; e) Pumps at rated speed; f) Pump constant speed band; g) 40 % feedwater flow; h) Natural circulation line (pump speed = 0); i) Pumps at minimum speed

The prerequisite for rapid power control is a nearly constant steam pressure in the reactor. Reactor pressure is controlled by a proportional-integral pressure regulator acting on the turbine control valves or the bypass control valves. From a process control viewpoint, the regulator is assigned to the reactor I & C but the equipment is really part of the turbine I & C system.

A three-element control system is used for reactor water level control. The elements for control during start-up are the start-up valves of the feedwater system and the variable-speed feedwater pumps during power operation.

Reactor Protection. The task of the reactor protection system is to continuously monitor selected process variables that are relevant to the safety of the nuclear power plant and its environment; to detect abnormal conditions; and to process these parameters to form signals for initiating reactor protection system action. Reactor protection must guarantee the following basic objectives:

Reactor scram
Residual heat removal
Prevention of unallowable radioactive release to the environment

If malfunctions escalate into accidents, automatic measures are initiated to control their consequences. The reactor protection system automatically triggers the necessary accident-related measures. No manual intervention by operating personnel is required for the first 30 min after onset of an accident.

Neutron-Flux Monitoring. The local power range monitoring system (LPRM) is used to monitor power distribution in the reactor core. It not only monitors the linear heat generation rate and the margin to film boiling, but also signals alarms on excessive conditions so that appropriate countermeasures can be initiated. The signals used for these purposes are output by LPRM detectors. These LPRM detectors measure the neutron flux, which is proportional to reactor power. Miniature neutron-sensitive ionization chambers are used as detectors, which are distributed uniformly over the core cross-section and the height of the core. Thus, information on the neutron-flux density is available for all fuel assemblies. The fixed in-core ionization chambers are checked and calibrated at regular intervals by traversing in-core probes. The LPRM detector output signals are used (1) by the reactor protection system to monitor the core and (2) by the process computer to monitor and control plant operation.

Turbine Instrumentation and Control. The turbine I & C is integrated into the general I & C concept of the overall plant. In certain cases, however, specific tasks or operational conditions require special solutions. The demands imposed on the dynamic behavior of the closed-loop control circuits regarding control speed, forces, and accuracy require a control system that is specifically tailored to the application involved. This also pertains to the turbine protection system, for which an especially high degree of reliability is required.

Non-Safety-Related Process Instrumentation and Control. The primary function of non-safety-related process I & C is to monitor and control the power plant from the control room. Non-safety-related process I & C forms the interface between operating personnel and power plant processes. It serves to optimize the basic conditions required for plant operation. Personnel are aided by a process computer to achieve this objective. Hard-wired protective logics are used in the control systems to execute simple protective functions. Closed-loop control systems not only provide for automatic process control but also maintain process conditions within specified limits.

3.1.2.3. Operation of the Boiling-Water Reactor

Operation of a reactor plant includes the various modes of plant operation and maintenance activities. Plant operation is divided into start-up, scheduled or unscheduled shutdown, and power operation with or without load following.

Start-up and Shutdown. The rate of plant start-up from the cold condition and run-up to full load is determined primarily by the allowable temperature gradients at the turbine and the reactor pressure vessel. First, the recirculation pumps are run up to a low speed; then the desired reactor power level is set (e.g., heating power by control rod withdrawal). The turbine is run up in the variable-pressure mode. After about 7 h, the required system pressure is attained in the reactor pressure vessel (see Fig. 41).

If reactor shutdown is scheduled, reactor power is reduced and the reactor is shut down by inserting all of the control rods. This causes the turbine to trip. The steam that is still generated by the decay heat in the reactor is dumped to the turbine condenser via the bypass station. The shutdown cooling system goes into operation as soon as the reactor pressure drops below 0.5 MPa.

If, for example, sudden malfunctions occur the plant is designed in such a way that it will automatically initiate an emergency shutdown (reactor scram and turbine trip).

Power Operation. During power operation, the plant is operated at an almost constant power level (base load). In Germany and other countries, however, nuclear power plants are designed to accommodate changes in load demands arising during power operation (load following). The limiting factors for the rates at which load changes may be made are not only the allowable temperature gradients, as in the case of start-up and shutdown, but also the mechanical properties of the fuel assemblies. The Grundremmingen BWR described here is designed for the following load change rates:

$\pm 120\,MW_e/min$	over the entire power range (ramp change)
$\pm 120\,MW_e$	between 70 and 90 % of rated reactor power (step change)
$-120\,MW_e$	between 100 and 90 % of rated reactor power (step change)

If these values are exceeded, a limitation immediately intervenes.

The plant is designed such that the following requirements are fulfilled at all times, not only during power operation but also during start-up and shutdown:

1) *Safety in the Event of Accidents*: If postulated accidents occur, the reactor must be able to be safely shut down and kept in a subcritical condition. The decay heat must be reliably removed over a prolonged period of time and radioactive releases maintained below the allowable limits.
2) *Safe Shutdown*: In case of loss of external load caused by abnormal events in the electrical distribution network, the plant must continue to supply its own auxiliary power requirements and must be available for reconnection to the power system.

Figure 41. Start-up and loading of boiling-water reactor nuclear power plant from cold condition
a) Temperature; b) Turbine speed; c) Pressure; d) Power

3) *Unit Availability*: In the event of failure of important components (e.g., reactor feed pumps or recirculation pumps), the functions of these components must be taken over immediately by standby components.

The reactor is shut down on the average of once a year for refueling and maintenance.

Refueling. When the fuel assemblies have reached the degree of burnup requiring their discharge from the core, the fuel still contains fissile material in the form of undepleted uranium-235 plus plutonium (plutonium-239 and -241), which is produced in the reactor. Consequently, economics dictates reprocessing of this fuel.

The replacement of about 25 % of the core load with fresh fuel gives the reactor enough excess reactivity to be operated continuously at full load for at least another year. Nuclear fuel developments have, in fact, made operating cycles of more than one year possible. During a one-year cycle, the loss of reactivity due to fuel burnup must be compensated for. This occurs through burnup of the neutron poison incorporated in the fuel and by gradually withdrawing the control rods. At the end of the cycle, all the control rods have been withdrawn from the core. If the reactor is operated beyond the end of the cycle (stretch-out operation), the output will decrease each day by about 0.33 % of the average daily output.

For refueling, the space above the reactor pressure vessel is flooded and the gate connecting to the spent fuel storage pool is opened. For radiation protection and residual heat removal reasons, the fuel assemblies are then discharged or shuffled underwater. The spent fuel assemblies can be kept in interim storage in the fuel pool for a prolonged period of time. Refueling requires approximately 2 to 4 weeks, depending on the size of the plant.

Maintenance. To guarantee reactor safety the plant must be inspected and maintained on a routine basis. This is carried out during the annual refueling outage. Maintenance and inspection requirements must be taken into account in the early planning stages of a plant; these include

1) Adequate accessibility for staff, replacement components, and equipment;
2) Development of automated inspection processes and equipment (e.g., manipulators for ultrasonic and eddy-current examinations);
3) Shielding measures and possibilities for decontamination;
4) Design of components to facilitate inspection and replacement;
5) Installation of monitoring systems (e.g., loose parts monitoring and leak detection systems) for timely identification of defects; and
6) Use of self-checking electronic modules.

The reason for this foresight during planning is to minimize radiation exposure of the personnel and to reduce outage periods and, consequently, costs.

3.1.2.4. Radioactive Releases to the Environment

The many years of experience gained with boiling-water reactors have shown that radioactive releases to the environment are small. The average annual release, (in Bq/a) of radioactive material from a German 1300-MW_e boiling-water reactor may be summarized as follows:

Gaseous effluents	
Noble gases	4×10^{12}
Aerosols	1×10^{7}
^{131}I	1×10^{8}
Liquid effluents	
Fission and activation products	5×10^{8}
Tritium	1×10^{12}

For modern power reactors, radioactive emissions from the stack are ca. 4×10^{12} Bq/a of noble fission gases, particularly ^{133}Xe, and ca. 1×10^{8} Bq/a of ^{131}I.

If normal habits are assumed, persons living in the vicinity of a nuclear power plant are subjected to an additional radiation dose of $< 10^{-2}$ m Sv/a (< 1 mrem/a) (for natural radiation doses see Section 2.3.2.1). Even if the most unfavorable hypothetical conditions are assumed (e.g., an infant is fed for a whole year exclusively on milk from a cow grazing at the most unfavorable receiving point in the immediate vicinity of the power plant), the calculated radiation dose is about 0.5 mSv/a (50 mrem/a) (0.9 mSv/a = 90 mrem/a is permissible for the thyroid gland according to Strahlenschutzverordnung).

The radioactivity released with liquid effluents is less than 5×10^{8} Bq /a, and additional tritium releases are about 1×10^{12} Bq /a, although the latter are unimportant because of the low radiotoxicity of tritium. Under the assumption that a resident receives the entire protein requirement from fish caught downstream of the plant discharge structure and, in addition, that drinking water comes exclusively from this water source, even then the additional radiation dose is $< 10^{-2}$ mSv/a (< 1 mrem/a).

3.1.2.5. SWR 1000

In 1992, a goup of German utilities and Siemens agreed on the development of a new BWR nuclear power plant with emphasis on replacing active safety systems by passive safety features, when possible. The new SWR (Siedewasserreaktor = BWR) will be designed for a net output of 750 MW_e.

The main design goals of this advanced concept are

1) Reliable control of the various design basis accidents
2) Low probalility of beyond-design basis accidents (core melt frequency)
3) Limitation of the impact of core melt accidents to the plant and the environment
4) High plant availability
5) Economic viability of the concept

The new features mainly function because of physical phenomena such as gravity, natural convection, evaporation; or inherent capability of the respective physical phenomena (i.e., temperature coefficient).

At the end of the conceptual phase, it was decided that the new requirements for the advanced SWR, especially economic aspects, were in favor of a concept with an increased power output: i.e., a thermal reactor power of 2778 MW and a net electric power output of 977 MW.

Various features have been modified compared with the existing designs:

1) The power density of the reactor core is reduced
2) Large water storage capacities inside and outside the reactor containment enable long grace periods and make operator interference unnecessary, especially during accidents
3) For transients and for accident control an emergency condenser and an additional containment cooling condenser enable passive decay heat removal from the core and from the containment, respectively
4) The safety functions reactor scram, containment isolation, and primary systems depressurization are backed up by passive systems
5) In case of a postulated core melt accident the installed cooling capacity is sufficiently conservative to prevent an impact on the structures inside the reactor system or on the environment

3.1.2.5.1. Nuclear Systems

Primary Circuit and its Main Characteristics. The nuclear steam supply system is located inside a concrete containment with steel liner and is surrounded by the reactor building. The main dimensions (22.8 m long and 7.0 m in inner diameter) of the reactor pressure vessel correspond to those of the reactor pressure vessel of the 1260 MW_e nuclear power plant in Krümmel (Germany). This means that a comparatively large water inventory is available above the core.

As in the case of large-capacity plants (1300 MW_e), the reactor is depressurized by discharging steam to the pressure suppression pool via safety-relief valves actuated by diverse pilot valves of both active and passive design. A further diverse means for pressure relief is provided by rupture disks. Once the reactor pressure has been sufficiently reduced, water can flow by gravity into the RPV from an elevated pool, the core flooding pool.

To reduce the buildup of pressure inside the drywell in the event of a loss-of-coolant accident, the SWR 1000 has vent pipes located outside the pressure suppression chamber, which terminate at the bottom in inclined ends discharging into the pressure suppression pool water. The routing of the relief lines and the location of the vent pipes outside the air space of the suppression chamber both constitute a further enhancement of safety, because these configurations rule out the possibility that steam can leak into the chamber air space.

The reactor is shut down either by inserting the control rods into the core using the control rod drives, by rapidly inserting all control rods using a hydraulic system, or by rapid injection of boron solution into the reactor water. The accumulators of the latter system, filled with a boron solution, perform two functions: first serving as a redundant backup to the water tanks of the scram system for rapid insertion of the control rods; and second providing a diverse means for stopping the nuclear fission in the core by injecting the boron solution into the reactor water.

Steam is conveyed to the turbine by three main steam lines and the feedwater is supplied to the reactor in two feedwater lines.

Reactor Core and Fuel Design. The main difference between the SWR 1000 core and previous designs is the reduced core height of 2800 mm (usually 3710 mm). Because of the reduced core height, the core can be positioned at a lower level inside the reactor pressure vessel, yielding a larger water volume above the core, which supports the accident control. The lowered core also implies a reduced length of the control rod drives, which means that the RPV can be located at a lower position inside the reactor building.

The reactor core consists of 648 fuel assemblies and 157 control elements. The internal square water channel provides increased and more uniform moderation and leads to a more even power distribution across the ATRIUM fuel assemblies. The ATRIUM design has a large hot-to-cold reactivity range ideal for longe cycles.

The fuel cycle lenght is planned for 24 month with a mean reload burnup of 65 GW · d/t. This requires fuel enrichment in the range of 5.3 wt % ^{235}U.

Fuel Handling and Transfer Systems. Refueling will be performed in a similar way as in the currently operating BWRs in Germany.

Primary Components.

Reactor Pressure Vessel. The reactor pressure vessel (Fig. 42) accommodates the reactor core and the reactor pressure vessel internals. The pressure vessel head is connected to the lower part of the RPV via a flange and fixed by bolts. The complete RPV is supported by brackets/pads in the building's structure. The inner surface of the RPV is lined with stabilized austenitic stainless steel. The pressure vessel is manufactured from 20MnMoNi55 steel. The alloy composition is specified in a very narrow range to optimize the ductility, stresses, and resistance against neutron radiation exposure.

All RPV *internals*, except for the core baffle, are removable to ease the accessibility for in-service inspection.

The six *reactor recirculation pumps* assure sufficient cooling of the reactor core. The power output of the pumps can be controlled by means of the speed control. In case of a failure of one pump, the flow through the core can be held constant by increasing the speed of the remaining pumps. The recirculation pumps are centrifugal pumps driven by wet motors, without mechanical seals and lubricated bearings.

Each of the three *main steam lines* is equipped with three isolation valves, two of which are system fluid-operated and one is motor-operated. One of the fluid-operated valves is located inside the containment, and the other outside it, together with the motor-operated valve.

The two *feedwater lines* are provided with three check valves as isolation valves, one of them is of diverse design. One valve is located inside the containment, while the other two valves are installed outside.

The outer valves of both steam and feedwater lines are located immediately adjacent to the containment.

Reactor Auxiliary Systems.

Safety-Related Systems. The design and mode of operation of the pressure relief system are basically the same as those of the pressure relief systems installed in operating BWR plants (see Section 3.1.2.1).

The application of eight pressure pulse transmitters to initiate reactor scram, containment isolation, RPV depressurization, and passive cooling of the reactor core – dependent on the water level in the RPV – represents a new feature of the design. Further passive systems are the four emergency condensers acting as heat sink for the RPV, as well as a flooding system with four flooding lines working by gravity as a low pressure injection system to control accidents.

Non-Safety-Related Systems. Two fully redundant residual heat removal trains are provided for removing heat from the reactor after shut down and depressurization. Each train consists of components of the RHR-system, closed cooling water and service water systems. Both RHR trains are equipped with pumps and heat exchangers designed to remove heat from the reactor under low-pressure conditions as well as heat from the containment. These systems can also be used to supply coolant to the reactor in case of an accident.

The *reactor water cleanup system*, which is basically a two-train design, continuously removes impurities such as fission and corrosion products from a part flow of reactor water diverted from the reactor. One of the two RHR trains has an additional shutdown filter to enhance reactor water purification while the plant is being shut down. These systems are located entirely inside the containment.

For cooling the control rod drives and also for supplying make-up water to the scram tanks following a reactor scram, a *control rod drive cooling system* is provided, which is equipped with two pumps sucking from the condensate storage tank. This system can be used to supply coolant to the RPV at high reactor pressure levels in case of loss of the normal feedwater supply.

The systems and components provided for reactor refueling, for the storage of new and spent fuel, and for handling RPV internals are not different in their design or mode of operation from those installed in current operating SWR plants. A novel feature is the integration of the spent fuel pool cooling and purification systems inside the pool. This dispenses with external connections to the pool below the water level, thereby reducing the potential for leakage from the pool, and eliminates some potentially highly contaminated circuits in the reactor building.

Operating Characteristics. Operating characteristics include:

1) The average annual availability over the plant service life will be > 87 %.
2) The load-following capability will meet the demands of the German load dispatcher.
3) The collective dose – as long-term average – of in-house and external personnel should be < 0.5 Sv/a (50 rem).
4) The duration of scheduled annual refueling outages shall be < 25 d.
5) The number of forced outages (over the plant service life) should be < 1/a.
6) The average discharge fuel burnup shall be between 50 000 and 65 000 MW · d/t U.
7) The plant shall permit stretch-out operation for 70 full-power days.
8) The reactor shall permit use of mixed-oxide fuel up to 50 % without any modifications to the concept, and up to 100 % with appropriate modifications.
9) The spent fuel storage in the reactor building shall be sufficient for at least 10 years of operation plus one entire core.

3.1.2.5.2. Turbine Generator Plant System

Turbine Generator Plant. The turbine is connected to the RPV by three main steam lines.

Since the bypass station is installed in parallel to the turbine, the entire steam volume generated inside the reactor can be dumped directly to the condenser. The main steam from the reactor is admitted to the high-pressure (HP) section of the turbine via combined isolation and control valves.

Figure 42. Reactor vessel comparison between SWR 1000 and NPP Krümmel

After partial expansion in the HP turbine section, the steam passes through a moisture separator without reheater to the three double-flow low-pressure (LP) sections of the turbine. The steam expands in the LP sections through several stages of bladings down to the condenser pressure.

Condensate and Feedwater Systems. The condensate collected in the hotwells of the three condensers is discharged into a common header supplying the main condensate pumps. The condensate passes a demineralizing system before being heated up to the final feedwater temperature in the feedwater heaters. The feedwater is injected via two feedwater lines into the reactor using speed-controlled feedwater pumps.

3.1.2.5.3. Instrumentation and Control Systems

The SWR 1000 will use a digital I and C system, covering the following areas:

Operational I and C
Safety-related I and C
Process control systems

Main Control Room. The entire plant process is controlled via the main instrument panel, independent of the mode of operation, i.e., during power operation, start-up, and shutdown of the plant. The process information is gathered in a raised instrument panel. Normal controlling and monitoring results can be adopted from flow diagrams and plasma screens.

Emergency Control Panel. An emergency control panel will be located in one of the emergency power supply buildings. In case of an accident, impact from outside, and non-availability of the main control room, shutdown of the reactor and decay heat removal can be initiated from the emergency control panel if it was not yet initialized by the automatic protection system. The emergency control panel is completely independent from the main control room and houses:

1) Control and supervision of both decay heat removal systems
2) Indication and documentation of special parameters of the incident monitoring system and long range I and C
3) Additional indicators and documentation and especially selected process parameter, necessary for function control of passive safety features.

Local Panels. Systems, that are necessary only for part-time operation and that need not be directly accessible from the control room, are operated from local control panels. Examples are the emergency diesel and sampling system.

Monitoring Equipment. The *neutron flux level* is directly monitored in the reactor core by means of fixed neutron detectors. The neutron flux monitoring system has the following functions:

1) Monitoring of the neutron flux density and periodic changes during shutdown conditions, during start-up from cold, subcritical conditions up to 125 % of nominal power
2) Monitoring of full power core conditions
3) Monitoring of the three-dimensional power distribution in the core

The proper functioning of the reactor depends on reliable monitoring of the following operation parameters: (1) reactor pressure, (2) reactor water level, (3) flow rate through the core, (4) live steam flow rate, and (5) temperature.

For control purposes, redundant measuring channels will be provided enabling the fulfillment of functions during operation, i.e., shutdown and incidents/accidents control.

Reactor Protection System and Other Safety Systems. The safety systems of the SWR 1000 consist of both active and passive safety features, and the latter will normally be actuated directly by process parameters without signal from the safety-related I and C.

The *safety-related I and C* generally detects and records accidents and/or incidents, and initiates active safety systems. In case of nonavailability or disturbances in active safety systems, the passive features take over to bring the nuclear power plant to safe condition.

The detection of an accident is identified by various process parameters, on which the uncertainties and the impact of common cause failures, based on direct measured information, can be governed.

If these requirements can not be fulfilled, a pressure increase inside the reactor vessel and/or a reactor water level decrease will lead to intervention of passive safety systems. A redundant design prevents immanent system failures due to loss of one redundancy because another will directly take over.

The redundancies are protected within the system and the reactor plant against failure-induced events, and each sub-system is protected against the other by physical separation. The redundancies are located in the two emergency diesel buildings, which are protected against external impacts. In each redundancy a control panel is included, from which the present plant status can be assessed, and manual actions to shut down the plant, for pressure reduction, and decay heat transfer can be initiated. A battery-backed energy supply system is incorporated in each of the redundancies. For function control of the passive safety features relevant process parameters are controlled and recorded. For these functions a separate battery-backed energy supply system is installed in the switchgear building.

During shutdown of the plant and opened reactor pressure vessel, repairs may be carried out in the two redundant safety systems. In such cases the passive safety features will be quite inactive, the functions normally dedicated to the safety systems have to be taken over by operational auxiliary systems.

3.1.2.5.4. Electrical Systems

The generator feeds into the 400 kV grid via the main transformer. The *auxiliary power* necessary for plant operation is extracted between the generator and the main transformer and fed into the 10 kV switchgear system via two auxiliary transformers. The auxiliary system is divided into two trains, each consisting of a 10 kV main distribution and a 690 V and 400 V low voltage distribution.

In the event of loss of auxiliary power supply, safe shutdown of the reactor plant requires that certain consumers are started or connected and that others remain in operation. Power supply to safety-related systems therefore can be divided into two categories:

1) Loads that may be de-energized for a period of 20 s during start-up of the diesel generating units are connected to the a.c. power distributions in the emergency power supply system.
2) Loads, which can not accept an interruption in operation or which have to be started

immediately, are connected to the secured power supply system. They are fed by the 220 V d.c. system or via a static d.c. – a.c. inverter and the connected 400 V distribution

With respect to accident control, the following process systems are available, besides passive safety features:

1) 2×100 % decay heat removal systems
2) 2×100 % additional systems with diverse emergency power consuming components

For emergency power supply of these systems a two train emergency system is installed.

3.1.2.5.5. Safety Concept

The safety concept of the SWR 1000 is based on accident prevention and mitigation. Innovative measures are introduced in the accident mitigation concept leading to remarkable higher safety standards.

With respect to prevention of accidents, all proven measures of current safety concepts assuring reliable operation are incorporated in the SWR 1000 plant design.

All requirements mentioned in accident prevention rules for PWRs in Germany have been considered, as far as they would be applicable to a BWR. Further precautions against hypothetical core melt accidents have been taken to limit the impact on the plant.

The new concept advantageously uses the reduced power density in the core and the large water reservoirs in the RPV, condensation chamber, and in the flooding pool. It also takes advantage of the active and passive system functions, which are redundant and diverse relative to each other.

Safety Systems and Features (Active, Passive, and Inherent). The necessary safety functions for accident control are ensured by redundant active systems. The design of the active systems takes into account the existence of additional passive systems to realize the deterministic redundancy concept in connection with the single failure strategy.

For fast shutdown of the reactor, a scram system with two independent trains activates the control rods, each train covering 50 % of the rods. Each train has a normal water and a borated water storage tank. They have two functions: the energy for insertion of the control rods is delivered from the system and the boric acid injection into the core is considered as a diverse shutdown system. In addition, the control rods can be moved into the core using electric drives, which are connected to the back-up energy supply system.

The main steam and feedwater lines are provided with three normally open isolation valves. One valve is located inside, the other two outside the containment.

The I and C system generates the signals for closing of the main steam valves via electromagnetic pilot valves, which operate in fail-safe mode. The check valves in the feedwater lines do not need any control signal.

Following an isolation from the main heat sink, the eight medium-operated safety and relief valves will blow steam down into the condensation chamber with its pressure suppression system to prevent excessive pressure in the RPV. These safety and relief valves also have the function to relieve the pressure in the RPV in a loss-of-coolant accident. To keep the main valves open during decreased RPV pressure they are mechanically locked.

Core flooding can be performed by two existing operational systems. High pressure injection is carried out with the control rod flushing system and low pressure injection with the residual heat removal system. Active components of the two-train systems feed all control rod drives with flushing and cooling water.

The two-train residual heat removal system will also be used as a low-pressure core flooding system during loss-of-coolant accidents. The water is transferred from the condensation chamber in the RPV under a pressure < 1 MPa. The feeding capacity of one train is sufficient for this operating mode.

Under accident conditions (i.e., failure of the main heat sink, loss-of-coolant accident), which lead to a separation from the main heat sink, the residual heat removal cooling system together with the condensation chamber of the wetwell (flooding pit-water cooling system) is used for heat transfer from the containment to an ultimate heat sink.

For passive *initiation* of reactor scram, isolation of main steam lines, and automatic depres-

surization of the RPV a passive pulse transmitter is installed. In case of a reduced RPV water level steam enters the transmitter and heat is transferred to a secondary medium that, in turn, will actuate, e.g., pilot valves.

In the scram system diverse passive pilot valves are installed in addition to the magnetic pilot valves in each train for passive initiation of scram.

The passive trail of the RPV pressure limitation system (see Fig. 43) includes redundant and diverse features. Besides the active magnetic pilot valves one extra passive spring-loaded pilot valve is planned for each of the eight safety and relief valves. In addition to the passive control of the safety and relief valves eight redundant and diverse rupture disks are installed. For pressure relief, which is only necessary during a LOCA, each of the safety and relief valves will be equipped with a diaphragm pilot valve actuated by a passive pulse transmitter.

Figure 43. SWR 1000 – Passive System

Pos.		Number
a	Emergency condenser	4
b	Safety-relief valve	8
c	Spring-loaded pilot valve	8
d	Diaphragm pilot valve	8
e	Passive pressure pulse transmitter	2×4
f	Rupture disk	8
g	Flooding line	4
h	Containment cooling condenser	4
i	Core flooding pool	
j	Pressure suppresion pool	
k	Vent pipes	15
l	Scram system	2

The *emergency condenser* has two functions: To release the decay heat to the flooding pool water; and to recycle the condensate back into the RPV is a fully passive component. It is located in the core flooding pool and is connected to the RPV by nonisolatable steam discharge and return lines. It starts operation upon dropping water level in the RPV.

For passive heat transfer from the containment, a separate containment cooling condenser will be installed, divided into 4×25 % units. The steam released into the containment by a LOCA or evaporation of water from the core flooding pool condenses in the containment cooling condenser and is recycled into the flooding pool. The condenser works by natural circulation.

Severe Accidents (Beyond Design Basis Accidents). In case of a core melt (which has a very low probability of occurrence), flooding lines from the core flooding pool will open to supply water to the outside of the RPV, so that the melt can be cooled while still inside the vessel. This ensures retention of most of the radioactive aerosols inside the containment.

The release of the most significant isotope, ^{137}Cs, amounts to approximately 10^{11} Bq. This is far below the level of 10^{14} Bq, which has been internationally accepted. The containment is inerted and the release of hydrogen would not lead to either combustion processes or an explosion. The design of the containment is such as to preclude loss of containment integrity under such pressure loadings.

3.1.2.5.6. Design

The location of the different buildings of the nuclear power plant can be seen from the plot plan (Fig. 44).

The central unit consists of the reactor building with integrated stack and the turbine building with integrated auxiliary building. The reactor auxiliary building with the entrance to the controlled area and the switchgear building with the main control room are located adjacent to these buildings.

At a certain distance from the power plant buildings and the cooling water entrance, there

Figure 44. SWR 1000 – Plot plan
UBA = Switchgear building; UJA = Containment; UJB = Reactor building; UKA = Auxiliary system building; UKB = Service building; UMA = Turbine building

Figure 45. Auxiliary and supporting systems in a nuclear power plant

are the buildings for the pump station, emergency diesel, and the auxiliary systems. Access by the staff during plant operation is possible via a personnel bridge from the social area of the auxiliary building.

Reactor Building. The reactor building accommodates all systems and components necessary for reactor operation and reactor protection. The complete fuel storage and handling facilities are located in the protected area. The other compartments not occupied by the primary system are used for installation of reactor auxiliary systems. Short cable and pipe routes are chosen. Redundancy is reached by physical separation of safety-related systems. The compact arrangement of systems and components enables optimal radiation protection and emergency protection. The reactor building accommodates the following installations:

1) Containment
2) Fuel handling and storage facilities
3) Scram tanks and pumps for control element drive flushing
4) Condesate tank
5) Ventilation and air conditioning systems for the controlled area
6) Radioactive waste concentrate tank
7) Off-gas system (delay beds)
8) Evaporation plant
9) Evaporator feed tank
10) Active waste collection tank
11) Condensate flushing tank of the main condensate system

The dimensions of the reactor building result from the size of the RPV and the condensation chamber, the flooding pool, the laydown area, and the fuel storage pool.

Containment. The pressure-retaining components of the reactor system (mainly the RPV) and the directly connected systems up to the second isolation valve are installed inside the containment.

Figure 46. General flow sheet of a PWR auxiliary system
a) Primary coolant pump; b) Regenerative heat exchanger; c) High-pressure cooler; d) Volume control surge tank; e) High-pressure charging pump; f) Boric acid storage tank; g) Boric acid and batch tank; h) Chemicals mixing tank; l) Ion exchanger; j) Spent resin tank; k) Degasifier; l) Condenser; m) Demineralized water degasifier; n) Destillate cooler; o) Recombiner; p) Predryer; q) Off-gas compressor; r) Gas dryer; s) Fission gas delay bed; t) Exhaust-air stack; u) Pressure tank; v) Residual heat exchanger; w) Residual heat removal pump; x) High-pressure safety injection pump; y) Refueling water tank; z) Spent fuel pit cooling water purification

The containment also incorporates some of the auxiliary systems.

The *plant components* are located below the condensation chamber. In this area the following components are installed: (1) residual heat removal pumps and coolers; (2) fast opening tank isolation valves for the control rod drives; (3) reactor water cleanup system pumps; and (4) reactor water cleaning coolers and filters.

The heat transfer out of the compartment is achieved by means of gas circulation coolers. The compartments are vented and can be entered by the staff.

The *drywell* accommodates the flooding pool and inner cylinder and houses the following components:

1) RPV
2) Feedwater and main steam lines and isolation valves
3) Safety and relief valves with exhaust pipe
4) First isolation valves of the residual heat removal system
5) Control rod drives and ring pipes of the Scram system
6) Recirculation pumps
7) Emergency condenser with condensate and steam pipes
8) Containment cooling condenser
9) Reactor water purification cleanup filter
10) Passive pulse transmitters
11) Flooding tubes
12) Measuring pipes
13) Vent pipes
14) Air circulation units (3×50 %)

The *wetwell* is filled with water up to about 40 %. For pressure suppression during incidents the released steam is injected into the water where it condenses. The vent pipes and the quencher tubes enter the water in the condensation chamber.

Turbine Building. The equipment of the water-steam cycle (including turbine and generator) the preheaters, and the feedwater system (including feedwater tank and feedwater pumps) are located in the turbine building. At the lowest floor the main cooling water pipes enter the building. The condensers are arranged transversal and occupy the room up to the turbine operating floor. The cooling water inlet and outlet of the condenser are held short. The preheaters are situated on the intermediate sealing adjacent to the turbine.

Other Buildings. The tanks used for wastewater storage and treatment are located in the *service building*.

The work shops, the waste treatment and storage facilities, and the central entrance to the controlled area are located in the *auxiliary system building*. The chosen design leads to short pipe and cable routes to the systems located in the reactor building. The auxiliary system building accommodates the following installations:

- Solid waste treatment
- Decontamination plant
- Fresh and off-air systems
- Hygiene rooms, especially for the controlled area (showers, lavatories, toilets)
- Laboratory
- Hot and cold work shop
- Office and storage rooms

The complete staff movement is being checked and guided. The entrance to the controlled area is located at about 13.30 m. For the transport of the components into the hot work shop the equipment has to pass the airlock.

The *switchgear building* accommodates two energy supply units, physically separated from each other, and constitutes the redundancy for the switchgear and I and C systems. Each part has its own cable, fresh, and off-air system.

3.1.2.5.7. Technical Data

General plant data	
Power plant output, net, MW_e	977
Reactor thermal output, MW_{th}	2778
Power plant efficiency, net, %	35.2
Reactor coolant system	
Primary coolant flow rate, kg/s	12000
Reactor core	
Active core hight, m	2.8
Average core power density, kW/L	48
Fuel material	sintered UO_2
Rod array	$12\times12-(4\times4)$ in square lattice
Number of fuel assemblies	648
Number of rods per assembly	128
Enrichment (range) of first core, wt %	4.95
Enrichment of reload fuel at equilibrium core, wt %	$\sim$5.3
Operating cycle length (fuel cycle length), months	24
Average discharge bunup of fuel, MW · d/t	65000
Cladding tube material	annealed, recrystallized Zr 2
Fuel channel/box material	Zr 4
Active length of fuel rods, mm	2800
Burnable absorber, strategy/material	Gd_2O_3 in fuel
Number of control rods	157
Drive mechanism	electromechanical
Soluble neutron absorber	Boron
Reactor pressure vessel	
Inner diameter of cylindrical shell, mm	7000
Total height, inside, mm	22800
Base material	
cylindrical shell and RPV head	20MnMoNi55 steel
lining	stainless steel
Design pressure, MPa	8.8

3.1.2.5.8. Project Status and Planned Schedule

The contact between Siemens and the German utilities runs for a period of 4 years, from 1995 to 1999. During this period, the necessary R & D activities shall be completed, the basic engineering work performed, and licensing documents prepared. The BWR shall be licensable in Germany in accordance with German rules, regulations and requirements, and also meet the European Utility Requirements. The conceptual design shall be established in early 1997.

Tests have been performed on the emergency condenser and these tests have confirmed the calculated performance; the full cooling capacity was attained earlier than expected and design margins could be quantified.

3.1.3. Safety and Operating Systems and Process Equipment for Light-Water Reactors

The special physical and technical conditions of energy production by nuclear fission, as well as radiation-related problems, call for special solutions that often differ from those employed in conventional thermal power plants. Requirements going beyond the conventional ones are set forth in pertinent legislation [82], regulations [83], codes [84], [85], and recommendations [86]. An additional standard for safety-relevant equipment in nuclear facilities is that such equipment must correspond to the state of the art. In addition, this equipment must be inspected at regular intervals and replaced when appropriate.

The three most important *safety criteria* in the design of safety systems are [87]:

1) Shutdown of the reactor must be possible from any operating condition.
2) Residual heat removal must be possible over an indefinite period.
3) Release of more than the permitted amounts of radioactive substances into the biosphere must be prevented.

In a pressurized-water reactor, the safety criteria (safety systems) and the requirements for power production (operating systems) are met as follows: grouped around the primary coolant loop are different systems connected directly to it. Depending on their function, these systems can be contaminated with different levels of radioactivity; therefore, they are located in the controlled area. Design of these systems and their components must take into account the following important *objectives* beyond the usual engineering rules:

1) The systems and equipment must be appropriately shielded because of the radioactivity they contain.
2) The components must often be placed in separate compartments so that they will be accessible and reparable during operation.
3) In many cases, processes must be remotely controlled or automated.
4) Extreme safety requirements lead to multiple redundancy in the design of many systems.

Figure 45 gives a general overview of the systems and equipment, with interconnections between related systems indicated. The way in which these systems work together is treated in more detail in the following sections (see also Fig. 46). Systems whose task is to fulfill the *safety criterion* are indicated in heavy outline in Figure 45. Systems relating to safety objectives (1) and (2) are, of course, directly connected to the nuclear reactor. Those intended to prevent the escape of radioactive substances [safety objective (3)] are located peripherally. Systems and equipment in between are needed chiefly for optimal power operation.

The *central system* includes the reactor with the primary loop and the pressurizing system connected directly to it (see page 46). Residual heat removal (RHR) and safety injection systems provide cooling for the reactor core in an operating status to be defined later.

The reactor has two independent shutdown systems. The first consists of a number of absorber rods. The second–the extraborating system–injects a "neutron poison" (concentrated boric acid solution) into the core when needed.

During reactor operation, a side stream is bled continuously from the primary loop, cleaned, and fed to the *volume control system*, from which it is returned to the primary loop. The cleanup system removes unwanted and interfering fission and corrosion products from the coolant. The volume control system evens out volume fluctuations in the primary loop and, together with the *chemical control system*, ensures that the coolant composition is optimal for the requirements imposed on it (see Section 3.1.3.1). Excess water is supplied to the coolant treatment system, where boric acid is removed from the coolant and the concentrated boric acid treated with water is stored separately for reinjection.

Surplus water from the reactor system, after gas stripping, is combined with wastewater to be treated. In the *wastewater treatment system* (see Section 3.1.3.7), the combined stream is cleaned up, decontaminated, and then released into the river water under monitoring. The *fission gases* obtained by stripping are led to the *off-gas treatment system*. After sufficient decay time the gas is diluted with exhaust air of the ventilation system and released to the atmosphere via the stack.

Radioactive solids are collected, compacted, and appropriately packaged. After interim stor-

age at the reactor site, they are shipped to the disposal facility (see Section 5.5.3). A similar procedure applies to *spent fuel assemblies*. After being unloaded from the reactor vessel, these are placed for interim storage in cooled fuel storage pools; after a sufficiently long decay time, they are packed in shielded shipping containers and transported to the reprocessing plant.

The *venting system* prevents the containment (i.e., the final barrier) from failing after a hypothetical accident, after a postulated blackout of all safety systems.

3.1.3.1. Volume Control System

The volume control system has the following tasks:

1) Removal of water from the primary system for purification;
2) Maintenance of the proper water level in the pressurizer during operation, start-up, and shutdown;
3) Provision of water for the sealing-fluid system of the primary coolant pumps;
4) Maintenance of a hydrogen excess in the coolant to prevent water radiolysis in the core; and
5) Injection of demineralized water and boric acid in the proportion required for reactor power control.

The maintenance of optimal coolant conditions required for the existing operating mode is attainable more easily and economically, if an appropriate part of the primary coolant stream is bled off downstream of the steam generator and brought to a low temperature (50 °C) and pressure (1.2 MPa, as shown in Fig. 46). The partial bleed off stream is controlled by the pressurizer water level; the feedwater flow stays constant. Since the mass flow rate in the pressure-reducing station downstream of the high-pressure cooler is controlled by the pressurizer water level, the level in the pressurizer can be held constant. After cleanup, the bypass coolant stream (at a reduced pressure of 1.2 MPa) flows back to the suction side of the high-pressure charging pumps. The proper hydrogen concentration is set either in the volume control surge tank itself or in a special gas saturator device. The latter has the advantage that the quantity of free hydrogen stored in the gas injector is very small compared to that in the surge tank; thus, the danger of fire or explosion is reduced.

Before reinjection into the primary loop, the coolant is preheated to ca. 280 °C in a recuperative heat exchanger. The sealing water for the primary coolant pumps is provided by a partial coolant stream that is led through very fine mechanical filters and then into the stuffing boxes of the pump shaft. Leakage from the shaft seal reenters the system downstream of the reducing station.

3.1.3.2. Chemicals Control System

The chemicals control system has the following tasks:

1) To store and feed in boric acid,
2) To feed in demineralized water, and
3) To inject chemicals for water chemistry control (see Section 3.1.5 for more details).

The excess reactivity of the core, which declines continuously throughout the reactor campaign (run), can be compensated by a variety of measures, including (1) absorber rods that can be inserted in the core as needed (see page 45); (2) burnable poisons that can be integrated into the fuel; and (3) water-soluble neutron poisons such as boric acid (see page 44). *Absorber rods* always have a nonuniform distribution in the core. As a result, the neutron spectrum is distorted. *Soluble poisons* have an optimal action because of their uniform distribution, so that a better burnup of fissile material can be achieved. Since no change of phase (i.e., evaporation) occurs in a PWR, this kind of reactor can be operated with a clearly controlled water chemistry (in contrast to a boiling-water reactor); in other words, the boron concentration can be adjusted to suit existing operational needs.

The required coolant boron concentration is ca. 1050 ppm boron on start-up after refueling and decreases by ca. 3 ppm/d at full power. The boron concentration is matched to the instantaneous reactor power demand. It follows the load cycles and ensures an optimal power density distribution in the core (lower boric acid concentration at higher power output and vice versa). For this purpose, either boric acid or demineralized water is supplied into the coolant on

the suction side of the high-pressure charging pumps (see Fig. 46). Chemical mixing tanks supply lithium [^{7}Li] hydroxide to adjust the pH during operation and hydrazine to bind free oxygen after every refueling or after repairs (see Section 3.1.5.1.1 for more details).

3.1.3.3. Primary Coolant Purification and Degasification System

The primary coolant bypass stream taken out downstream of the steam generator is passed through the coolant purification and degasification system (Fig. 46) to limit the concentration of corrosion and fission products (^{131}I, ^{58}Co, ^{60}Co, ^{137}Cs, ^{133}Xe, ^{85}Kr, etc.). Coolant purification involves a combination of mechanical and ion-exchange filters. The variety and extremely low concentrations of isotopes to be removed, as well as the relatively high concentration of added chemicals, which may be expensive (^{7}Li), call for careful monitoring of this process to achieve the highest possible decontamination factors for radioisotopes and the lowest possible consumption of ^{7}Li.

The ion-exchange resin, with a service life of one or two years, is not regenerated after it becomes exhausted but is disposed of as radioactive waste. Regeneration would again place the radioisotopes in highly dilute solutions, which would be unsuitable for reprocessing.

The water in the fuel storage pool is cleaned in a similar way to the coolant. For practical reasons, these two systems are located close to each other because of common components (e.g., resin flushing pump). Gas strippers connected downstream of the filter system can be employed to remove noble-gas fission products from the coolant. These gases should be removed before opening the closure head of the reactor vessel for refueling.

3.1.3.4. Primary Coolant Storage and Treatment System

The functions of the primary coolant storage and treatment system are as follows:

1) To receive and buffer incoming coolant,
2) To separate boric acid and water (distillation),
3) To store demineralized water and boric acid for reuse, and
4) To prepare excess coolant for discharge.

The coolant resulting from changes in boric acid concentration and the excess water from expansion when the temperature is increased from 50 to 300 °C on reactor start-up are retained in *primary water storage tanks* (see Fig. 46). Water and boric acid are then separated in coolant evaporators. The relatively high steam volatility of boric acid must be considered in evaporator design. Concentrate (4 % H_3BO_3) is taken out continuously of the evaporator's reboiler and led to the *boric acid tank*. The distillate (demineralized water) passes back to the primary water storage tank that was drained for this operation. The tanks are automatically switched from water containing boric acid (coolant) to demineralized water, and the evaporator is automatically turned on and off, so that storage volume and operator effort can be kept to a minimum.

The closed coolant cycle not only offers economic benefit but also minimizes the release of radioactivity. In three special cases, however, water or boric acid may have to be released from the loop:

1) To make up the effective boron isotope (^{10}B), whose concentration declines during operation as a result of (n, γ) reactions
2) To limit unfilterable tritium (^{3}H), which is produced from hydrogen or boron and escapes from the fuel element as a fission product
3) To prevent overfilling of the primary coolant system

Before it is discharged to the environment, the coolant is evaporated, degasified, and condensed to remove all dissolved or gaseous radionuclides; the resulting water is then monitored in the wastewater treatment system and may have to be retreated there.

3.1.3.5. Off-Gas Treatment System

Nitrogen is used as blanket gas in all systems where primary coolant is stored or processed. To prevent noble fission gases from escaping into the building atmosphere through leaks in

the systems, a slight subatmospheric pressure is maintained in all tanks with the aid of the off-gas system (left in Fig. 46). As a result, both fission gases and hydrogen (from conditioning of the coolant; see Section 3.1.5.1) are present in the gas blankets of the tanks; if leaks occur in the system walls, atmospheric oxygen may also be present. Excessive hydrogen levels (danger of explosion) are prevented by using the off-gas system compressors to purge all tanks continuously with recirculating gas (96 – 100 % N_2, 1 – 3 % H_2, < 1 % O_2, $\leq$ 0.01 % noble gases). In this way, the hydrogen concentration is equalized and kept under the ignition limit (4 %) (Fig. 46 shows only the purging of the primary water storage tanks and one of the two compressors). The recirculating compressor draws the gas mixture through a recombiner, where hydrogen is catalytically burned with added oxygen. Protecting the recombiner area against explosion is especially important.

A bypass of the purge gas stream is led through a *delay line*, an adsorption unit operated at saturated equilibrium. In the relatively long path through this unit, individual gas molecules have several opportunities to undergo exchange processes with similar and identical molecules on the activated carbon (at kinetic equilibrium). The holdup unit is sized so that the hold up time of individual radioactive noble gases is roughly 10 times the half-life $t_{1/2}$ of the most important radioactive isotopes (^{133}Xe, $t_{1/2} = 5.65$ d; ^{85}Kr, $t_{1/2} = 4.4$ h). The radioactivity is thus reduced by a factor of $2^{10} \approx 1000$; for practical purposes, this is sufficient. Gas cleaned in this way is returned to the main stream. If maintaining lower pressure in the off-gas system requires the extraction of small amounts of gas because of inward leakages, this gas is automatically bled off downstream of the delay line, mixed with exhaust air, and bled to the stack.

Besides the methods described here, other options exist for the treatment of radioactive noble gases. Examples are storage in cyclically operated tank batteries (charging, decay, release), chemisorption processes, and low-temperature adsorption. Low-temperature adsorption has the advantage of better separation factors and, under some conditions, longer storage (decay) times. For practical use, however, the method described above is quite adequate.

The selective *absorbing* power of certain organic compounds (such as Frigen) can also be used to hold up the noble gases.

The reduction of radioactive noble-gas releases to extremely low levels is limited because some leaks cannot be prevented in systems filled with high pressure primary coolant; that is, a certain amount of noble gases can escape without passing through the off-gas treatment system.

3.1.3.6. Residual Heat Removal and Emergency Cooling System

After reactor shutdown in normal operation and during incidents or accidents, the residual heat removal and emergency cooling system removes the remaining decay heat. The heat source in a nuclear power plant differs from that in conventional steam boiler plants in several ways, one of which is that the heat production of the fuel assemblies cannot be reduced to an arbitrary extent. Some residual heat occurs even after shutdown because the radioactive fission products continue to decay (see Section 1.3.10).

Since this residual heat is an inherent quality of the reactor, core cooling must be ensured by a large safety factor to prevent damage to the fuel assemblies and the release of radioactive fission products. The RHR system is, therefore, highly redundant in design. Because safety regulations require operability of the heat removal system in the event of an additional single failure in passive systems that do not depend directly on the immediate damage, redundant systems must be totally independent of each other.

The importance of these systems in view of safety objective (item 2 in second sequential list in Section 3.1.3) has led to precise statements of their design criteria [88]. Residual heat removal is handled by a four-loop arrangement with four equivalent partial systems (trains), any one of which can deliver 50 % of the rated cooling requirement even in the case of the maximum credible accident. Each of these four trains has a cooling chain independent of all the others. The loop filled with primary coolant–the first link in the cooling chain–gives up its heat to a closed component cooling loop. Only this loop is cooled with water from open sources (rivers, ponds, cooling towers, etc.). The chain arrangement means that radioactivity can-

not escape from the primary coolant loop into the open atmosphere in any operating or accident situations. Safety regulations also mandate closed-component cooling systems for all cooling points in other systems that contain radioactive media.

The extreme high reliability of the RHR system requires that no two cooling chains be situated close together, so that a single failure in one redundancy cannot entail a damage in the nearby redundant train. Naturally, the safety systems have independent emergency power supplies and are also protected against earthquakes. Another essential point is that not only the mechanical parts of the cooling chains, but also the entire electrical power and transmission systems, are physically separated. Appropriate fire protection measures prevent damage to more than one cooling system at a time in case of fire.

An example of a cooling system whose layout corresponds to the state of the art is illustrated in Figure 46 (right of center). The following tasks must be carried out:

1) Removal of residual core heat on normal shutdown; cooling down to near room temperature if necessary
2) Flooding and draining of the reactor well during refueling
3) Residual heat removal from irradiated fuel assemblies stored in the fuel storage pool
4) Flooding and emergency cooling of the core after a loss-of-coolant accident (maximum credible accident: loss of coolant due to total rapture of a primary loop pipe)

Each system is provided with adequate reserves of borated water located in the refueling water tanks. Low-pressure or high-pressure injection pumps draw coolant from these tanks as needed. The suction side of the low-pressure safety injection pump is also connected to the containment sump; this branch is always closed in normal operation.

One train of the *low-pressure safety injection system* includes the refueling water tank, the RHR pump, and the RHR system heat exchanger. Inside the containment, the system is subdivided into the *hot leg*, which joins the primary loop between the reactor pressure vessel and the steam generator, and the *cold leg*, which is located between the reactor pressure vessel and the primary coolant pump. The accumulators are also part of the low-pressure injection system. They store concentrated borated water under higher pressure (e.g., 4.0 MPa). In normal operation, the control elements (check valves) in the hot leg can be opened freely after the reactor has been shut down and the pressure reduced sufficiently. For the residual heat removal from the core, the primary coolant is taken out through this piping and reinjected through the RHR cooler with the RHR pump (also called the low-pressure injection pump) into the cold leg.

A train of the *high-pressure safety injection system* includes essentially the high-pressure safety injection pump with associated piping and fittings. The high/low-pressure and pressurizer feed lines are combined before injection into the primary loop.

As Figure 46 shows, the injection pumps and accumulators are isolated from the reactor core only by check valves (two in series at each connection). In normal operation, the large pressure difference keeps these closed. If, a large leak permits coolant to escape from the primary loop, the primary pressure decreases rapidly and the lower pressure automatically allows injection. In this way, the system is made highly reliable. When the RHR loops (RHR pumps and RHR system heat exchangers) are activated after reactor shutdown, the residual heat of the core in any normal operating status can be removed regardless of whether the fuel assemblies are all in the reactor, all in the fuel storage pool, or some in each.

The borated water stored in the *refueling water tanks* is used to flood the reactor compartment above the pressure vessel during refueling. The diverse functions of this safety system are described by means of its main operation modes. Depending on the size of a possible leakage the pressure in the primary loop falls slowly or rapidly. Then the reserve water from the refueling tank is immediately injected by the high-pressure safety injection pumps (low mass flow rate, high head) or the RHR pumps (high mass flow rate, low head). In the event of a *small* or *medium-sized leak*, the high-pressure safety injection pumps come into play. After the pressure in the primary loop has fallen and the reserve water from the refueling water tank has been injected, the RHR pumps reinject water from the sump. In the *design case*

(the maximum credible accident for which the cooling system is designed e.g., total failure of a primary coolant pipe), the accumulators automatically go into action first to flood the core immediately. Flooding is then continued by the RHR pumps. As soon as the refueling water tank is completely empty, further core cooling occurs in a semiopen loop: containment sump → RHR pump → RHR system heat exchanger → primary injection → reactor pressure vessel → overflow at leak → containment sump.

The fourfold redundancy of the system enables one of the trains to be repaired during operation. Even in this case, one further train can become unavailable because of single failures. The remaining two trains ensure core cooling. The containment, inside which all components in contact with high pressure and primary coolant are located, is designed so that all the steam escaping from the primary loop in an accident is retained. Cooling of the reactor core can thus be continued for any length of time until measures have been taken to remedy the damage.

The approach described above is for any conceivable accident with an extremely high probability. After Three Mile Island (1979), and especially after Chernobyl (1986), hypothetical design accidents more serious than those previously used were defined. One such is the postulated *station blackout*: failure of all electrical power, including all diesel-powered generators, possibly, but not necessarily, combined with a loss-of- coolant accident. Analysis of such accidents yields scenarios involving a core meltdown. To cope with these accidents, it is advisable to provide cooling by passive measures (without the use of energy) involving no pumps (e.g., by natural convection). In addition, there are considerations to maintain the possibly molten core in a coolable configuration even outside the reactor pressure vessel by proper design measures in the containment sump area.

One consequence of such hypothetical accidents would be the formation of *large amounts of hydrogen*; after a meltdown, this could be produced either by metal – water reactions in the reactor vessel, after a possible core melting or from the water contained in concrete structures. In parallel with hydrogen formation or in a later phase of the scenario, decay heat from the molten core could cause an increase in pressure in the containment and, ultimately, uncontrolled failure (leakage) of the containment. Containment failure is prevented by the *pressure relief system*, a new feature of all German reactors that can serve as an example of compliance with the legislated requirement that equipment keep up with the state of the art. The passive pressure relief system consists of a relief line, attached to the containment, that vents the overpressure to the atmosphere through an apparatus with a venturi scrubber and an aerosol filter. The filters are sized to prevent inadmissible contamination of the environment.

Another means to limit the pressure build-up in the containment after such a severe accident is a *containment heat removal system* equipped with an independent cooling chain and electrical power supply. Such an *active system* would offer the possibility to reduce the pressure in the containment to atmospheric level and would thus limit the release of the containment atmosphere into the environment. Together with an appropriate confinement design (e.g., double wall containment) the consequences of even a severe accident would be limited to the plant site itself–a requirement which is part of the new atomic law in Germany and valid for the next generation of nuclear power plants.

A variety of ways are being studied to control the danger of detonation resulting from high hydrogen levels in the containment. The problem is most likely to be solved by some combination involving autarkic igniters and large-area hydrogen oxygen recombiners. Such a system could be adapted to existing plants, such as the pressure relief system or the containment heat removal system . The consistent design of an entire facility against all possible hypothetical accidents will depend on analysis and developmental work that is not yet complete.

3.1.3.7. Waste Treatment

To keep environmental pollution as low as possible, all media leaving the controlled area must be treated. *Wastewater* is intercepted by drains as close as possible to the source and led to a central collecting station. Depending on its activity as well as chemical and physical qualities, the wastewater is subjected to mechanical fil-

tering, evaporation, or ion- exchange treatment. The maximum decontamination factor (ratio of inlet radioactivity to end product radioactivity) varies from ca. 10 for mechanical filtering to $10^3 - 10^5$ for evaporation. A variety of processing steps can also be configured in series.

Decontaminated water is led to monitoring tanks, checked for radioactivity, and released only when below the allowed radioactivity limit. All wastewater from the controlled area must be discharged through a single pipe equipped with recording instruments that measure the mass flow and the radioactivity. If the permissible activity level of 10^{-4} Ci/m^3 (3.7×10^6 Bq/m) is exceeded, a valve in the discharge pipe closes automatically.

Concentrated low- and intermediate-level wastes (filtrate, ion-exchange resins, evaporator sludge) must be converted to storable products. Under regulations in most countries, this waste is incorporated into matrices with low water solubility that can tolerate the expected radiation dose for at least 100 years without substantial physical or chemical changes. Suitable matrix materials are bitumen, concrete, and certain plastics (see Section 5.5.2 for more details).

Solid radioactive wastes (mechanical filter media, contaminated garments, machine parts etc.) are also gathered at central points, compacted (in ram presses), packed in standard radiation-proof and radiation-resistant containers, similar to those used in wastewater treatment, and shipped to a disposal facility such as an old mine (see Section 5.5.4 for more details).

3.1.3.8. Ventilation System

The ventilation system serving the controlled area must perform the following tasks:

1) Maintain the air temperature and humidity at specified levels,
2) Maintain specified pressure differences and properly directed flows, and
3) Lower the airborne radioactivity in the controlled area (to protect operating personnel) and limit the activity discharged through the stack (to protect the environment).

Compartments to be ventilated are grouped in accordance with the following criteria:

1) Compartments to which access is not allowed during normal operation because of intense direct radiation. There is mostly large-scale heat generation in such compartments (especially those containing high-pressure equipment).
2) Compartments to which access is allowed during normal operation (including access only after equipment is shut down and reactivity is sufficiently reduced).
3) Compartments to which access is freely allowed (control rooms, passageways, etc.).

In the first group of compartments, closed air circuits remove the dissipated heat in heat exchangers. Both air circulation and fresh-air cooling can be employed in the second group, depending on equipment and operating costs. Freely accessible compartments are supplied with fresh air. A reduced pressure of ca. 0.05 – 0.2 kPa relative to the outside atmosphere is maintained in all compartments in the controlled area; compartments with higher activity levels are held at lower pressures than those with lower levels.

The mass flow of the exhaust air consists of the fresh air fed into the second and third compartments and the leakage air that originates from the reduced pressure in the entire control area. If necessary, this air must be passed through aerosol filters (fine mechanical filters) or, if radioactive iodine (chiefly ^{131}I) is present, through activated carbon filters.

3.1.4. Materials for Light-Water Reactors

The materials used in the construction of pressurized-water reactors and boiling-water reactors are similar, and they are discussed together here. Any differences are pointed out in the discussion.

The selection of materials for full-scale industrial equipment depends on the qualities required. These attributes vary between different applications, and are also governed by the service conditions and the safety profile.

Material selection for systems and components of light-water reactors differs from that for fossil-fueled power plants because of significant differences in design, service conditions, and postulated safety margins. This counts, above

all, for the primary coolant and some components of the water – steam circuit and in the nuclear auxiliary systems [89].

Table 21. Properties of Zircaloy-2 (Zry 2) and Zircaloy-4 (Zry 4)

Properties	Zircaloy-2	Zircaloy-4
Chemical composition, wt %		
Sn	1.20 – 1.70	1.20 – 1.70
Fe	0.07 – 0.20	0.18 – 0.24
Cr	0.05 – 0.15	0.07 – 0.13
Ni	0.03 – 0.08	
Fe + Cr		< 0.28
Fe + Cr + Ni	0.18 – 0.38	
Modulus of elasticity E, MPa	96 000	
Strength values at room temperature (recrystallized)		
Yield strength $R_{p\,0.2}$, MPa	≤ 241	
Ultimate tensile strength R_m, MPa	≤ 413	
Total elongation, %	≤ 20	
Mean coefficient of thermal expansion α, K^{-1}	ca. 6.5×10^{-6}	
Density ϱ, g/cm^3	6.55	
Macroscopic effective thermal-neutron cross-section ε_a, cm^{-1}	0.0079	

3.1.4.1. Materials for the Core Region

Materials in the core include those used for fuel assemblies (aside from fuel, see Section 5.3.1) and for control and shut-down (both control and shut-down elements have an identical design) elements, which must meet fundamentally different requirements, as well as those for the pressure vessel internals (core structure).

Materials for Fuel Assemblies. Fuel-assembly materials must have the following properties:

1) Low neutron absorption
2) Dimensional stability and microstructural stability under neutron bombardment
3) Corrosion resistance with respect to the water or steam coolant (fuel cladding tubes must also be compatible with the fuel)
4) Mechanical stability (i.e., strength and ductility)

Light-water reactor fuel assemblies consist of cladding tubes for fuel rods (which separate fuel and coolant), top and bottom end pieces, intermediate spacer grids, and guide tubes (see Section 5.3.1).

Virtually the only alloys used for *cladding tubes* in present-day Western LWRs are Zircaloy-2 (BWRs) and Zircaloy-4 (PWRs) (see Table 21). In LWRs of the former USSR design, the principal cladding tube alloy is Zr1Nb.

Other *structural materials* are chiefly Zircaloy-4 plates for spacer grids; Zircaloy-2 and 4 for fuel-rod end plugs; cast or forged and welded austenitic stainless steel (i.e., 1.4550) for top and bottom end pieces and Inconel X (BWRs) or Inconel 718 (PWRs) for spacer springs.

More recently, new zirconium alloys for cladding tubes with improved corrosion resistance are under development. This work is in progress in several countries. They are expected to be commercially available around 1993.

Zirconium technology can serve as a model for the deliberate development of new materials for a new application [90], [91], [92].

The primary industrial process for obtaining zirconium today is from zircon ($ZrSiO_4$), which occurs extensively on the coast of Australia in the required quality. The undesirable companion element hafnium (→ Hafnium and Hafnium Compounds, Chap. 5.2.,→ Zirconium and Zirconium Compounds, Chap. 1.4.2.) is separated; the zircon concentrate is reacted with chlorine to form zirconium tetrachloride ($ZrCl_4$), and this product is reduced with pure magnesium by the Kroll process (→ Zirconium and Zirconium Compounds, Chap. 1.4.3.) [93].

All zirconium alloys are melted in high-vacuum electric-arc furnaces with consumable electrodes; remelting generally follows. Semifinished product is obtained by conventional hot forming (forging, hot extrusion). Since zirconium is sensitive to gas absorption (oxygen, nitrogen) at high temperature, the heat treatment of semifinished and finished products is usually carried out under vacuum. In cold working (rolling, drawing, rocking), the anisotropic deformability of zirconium alloys in the (hexagonal) alpha structure (below ca. 800 °C) must be taken into account. The textures formed can influence service properties (e.g., radiation-induced growth) [94].

Zirconium is sufficiently stable against nuclear reactions initiated by neutron bombardment. The nuclear-grade metal (ASTM B 350 Grade R 60001) has a macroscopic effective

thermal neutron cross-section $\varepsilon_a = 0.0079\,cm^{-1}$ (for comparison, iron has an ε_a of $0.22\,cm^{-1}$).

Corrosion [95] at high pressure (7.0 – 15.0 MPa) in hot water or steam up to 360 °C is characterized by the formation of a usually adherent oxide film (ZrO_2):

$$Zr + 2\,H_2O \rightarrow ZrO_2 + 2\,H_2$$

In *pressurized-water reactors* with high thermal efficiency, this form of cladding corrosion has become a design limiting factor. The rate of corrosion is governed largely by the temperature at the metal – coolant interface. In *boiling-water reactors*, locally accelerated "nodular" corrosion of Zircaloy-2 and Zircaloy-4 cladding and structural parts has led to increased attention internationally. This type of corrosion depends chiefly on irradiation and water chemistry.

Along with increased corrosion, the absorption of hydrogen in zirconium alloys has become increasingly important. This effect results in part from the corrosion reaction and in part from the hydrogen excess (ca. 2 – 4 ppm) present in PWR coolant (see Section 3.1.5). High hydrogen absorption in zirconium alloys leads to the formation of hydrides and thus to embrittlement of the material.

The mechanical properties of Zircaloys can be regarded as satisfactory. They have a texture-dependent tendency to growth, induced by neutron irradiation, although the effect is quite manageable.

Materials for Control and Shut-Down Elements. Absorber materials must satisfy the following requirements:

1) High neutron-absorbing capacity in the thermal and epithermal ranges (< 0.01 MeV)
2) Dimensional stability under (neutron) irradiation
3) Mechanical stability
4) Corrosion resistance if the materials are used without protection

In *boiling-water reactors* the principal absorber material for control and shutdown rods today is boron carbide (B_4C), usually in granulated form (grain size, ca. 100 µm, ^{10}B content 18.9 %). Powdered boron carbide is charged into tubes or hollow drilled plates of austenitic stainless steel (1.4550), which are assembled into cross-shaped control elements.

The effective isotope ^{10}B is transformed to ^{7}Li and helium by (n, α) reactions. The associated swelling of boron carbide must be taken into consideration in the design of the control and shut-down devices. As an alternative some of the boron carbide-filled rods have been replaced by rods or strips of solid hafnium, which is generally used without cladding because of its high corrosion resistance.

For *pressurized-water reactors*, a ternary alloy of silver, indium, and cadmium (80 – 15 – 5 wt %) is used as the absorber material in control, and shut- down elements. The alloy is made into rod shape and inserted into tubes of austenitic stainless steel (i.e., 1.4550), which are closed by tight welding. In contrast to boron carbide, the neutron absorption reaction of this material is based on (n, γ) reactions, which cause little change in the density and mechanical properties of the absorber material.

In addition to absorber materials in the control and shut- down devices of BWRs and PWRs, gadolinium oxide (Gd_2O_3) is added to uranium dioxide fuel as a burnable absorber (poison; see Sections 3.1.1 and 3.1.2).

3.1.4.2. Materials for Components of the Nuclear Steam Supply System

Two essentially different material concepts are employed in the primary loops of pressurized-water reactors:

1) All components, including connecting piping, are made of low-alloy ferritic steels. Component surfaces in contact with the primary coolant water–especially in modern designs–have a weld-deposited cladding of austenitic stainless steel to minimize the ingress of corrosion products in the core region of the reactor pressure vessel.
2) In mixed construction, low-alloy ferritic steels are used for the large components (RPV, steam generator, pressurizer); the surfaces in contact with the media are weld cladded as in item 1. The main coolant piping, main coolant pumps, and any gate valves present in the primary loop are made of solid austenitic stainless steel as structural material.

Table 22. Low-alloy materials

Low-Alloy Ferritic Steels. Forgings, plates, and castings are made mainly of the following steel types: Ni – Mo – Cr (22 NiMoCr 37, SA 508 cl 2) [96] or Mn – Mo – Ni (20 MnMoNi 55, SA 508 cl 3, SA 533 Gr B, 16 MND 5) [97] in the United States and Europe, and Cr – Mo (15 Cr 2 MFA, 15 Cr 2 NMFAA) [98] in Soviet designs (Table 22). The special requirements on weldability (weld cladding and joining), uniformity of chemical composition, and mechanical and technological properties – even for very thick-walled components (e.g., up to ca. 500 mm for the pressure vessel flange, up to ca. 650 mm for the steam generator tube sheet) and extremely heavy forgings (up to 575 t) – have sometimes led to complex and sophisticated qualification measures.

The toughness of the steels is especially important. Notched-bar impact tests, drop-weight tests, and in some cases fracture-mechanics tests are performed to ensure that the materials are tough enough for all service conditions.

For the cylindrical parts of the pressure vessel wall that are located in the neutron flux, the stability of the material against neutron irradiation demands special attention. The radiation sensitivity–in particular, the loss of toughness as a function of neutron irradiation–is substantially enhanced by the alloying elements copper and phosphorus. The first systematic investigation of the effect of copper and phosphorus was published in the United States 1969 [99]. Currently applicable regulations restrict these elements, for example, copper ≤ 0.10 % and phosphorus ≤ 0.012 % in the radiation-affected region of the pressure vessel [100].

Austenitic Stainless Steels. For service at ca. 320 °C and under water chemistry conditions of light-water reactors, the main candidate steels are austenitic 18 % Cr and 10 % Ni types, such as X 6 CrNiNb 18 10 (1.4550), AISI 304, AISI 316, and AISI 347 (see Table 23). To guard against intergranular stress-corrosion cracking in the PWR and BWR environments, those parts or surfaces in the primary loops and auxiliary systems that are in contact with the media are made of either austenitic stainless steels stabilized with niobium or titanium, or extra-low-carbon (ELC) steel (ELC qualities with C ≤ 0.002 %), for which the chemical composition is strictly controlled by special quality specifications (e.g., AISI 316 NG) [101], [102].

The reactor *pressure vessel internals* are the largest individual components in light-water reactors, which are fabricated entirely of highly corrosion-resistant austenitic stainless steel. The reasons for this choice include not only the high corrosion resistance with respect to the coolant and the associated low metal loss rate (< 5 µm/a), but also the low sensitivity of the material properties of this steel for changes related to neutron irradiation.

Both the pressure vessel internals exposed directly to the neutron flux and all other components in contact with the primary coolant (whose corrosion can release corrosion products into the radiation field) call for a steel with a low content of alloying elements and impurities that form long-lived radioisotopes.

Nickel-Rich Alloys The main use of these alloys is in *steam generator tubes* (see Tables 23 und 24), which function as a barrier between the radioactive primary coolant and the activity-free secondary coolant and must therefore meet the most stringent requirement with respect to leak tightness. The principal criterion for tubing material selection is, therefore, corrosion resistance with respect to the high-temperature primary and secondary coolant water. Chemistry guidelines for replacment steam generators of the Siemens – KWU type are listed in Table 25.

The choice of materials for the tube bundles is currently limited to austenitic and nickel-based alloys based on the Fe – Cr – Ni system, which offer the optimum combination of mechanical, thermal, and chemical properties. The materials used for the steam generator tubing in the first PWR plants, up to 1967, were austenitic stainless steels (AISI 304, 316, or 347) and similar grades are still employed in the Russian VVER horizontal steam generators. The corrosion behavior of these generators was generally satisfactory, and in view of the problems subsequently encountered with one of the replacement materials, some people regretted that these grades were not conserved.

Hard Facing Materials. Many years of operating experience have shown that the activation products of the loop materials determine buildup of the radiation dose in the var-

ious systems of the reactor. Because of its long half-life and the high energy of the emitted radiation, ^{60}Co makes the principal contribution. Analytical investigations have shown that cobalt-containing hard facings on fittings and of valves and parts of the pressure vessel internals are of prime importance. In addition to optimization of the primary coolant chemistry, the use of cobalt-free hard-facing materials is thus important. Materials based on C – Cr – Fe and C – Cr – Mn – Si – Fe having wear and workability properties comparable to those of cobalt-containing materials are used as substitutes [106].

3.1.5. Water Chemistry of Light-Water Reactors

3.1.5.1. Water Chemistry of Pressurized-Water Reactors

3.1.5.1.1. Primary Coolant System

The primary coolant serves as a moderator and as the medium for transporting heat from the core to the steam generators. Hence, it must not endanger plant operation by the corrosion of materials and consequences thereof. The task of water chemistry can be divided into the following main points:

1) Metal release rates of the structural materials should be minimal
2) The occurrence of localized forms of corrosion should be counteracted

3) The transport and deposition of corrosion products must be influenced in such a manner that contamination of the primary coolant system is kept low
4) The deposition of corrosion products on heat-transfer surfaces, particularly on fuel assemblies, should be prevented as far as possible
5) The radiolytic formation of oxygen should be suppressed

In certain instances, situations may be encountered where conditions of water chemistry are optimum for achieving one goal but are not at optimum with respect to other goals. Thus, the water chemistry specifications must define parameters to achieve a balance among the five objectives, taking into account that highest priority is assigned to materials and fuel integrity. This demonstrates the close connection between choice of materials and water chemistry. Although the other goals are in the second line of priority, they cannot be ignored. The water chemistry conditions specified to fulfill these requirements apply to the materials (see Section 3.1.4), which are in contact with the primary coolant:

1) Austenitic stainless steels for components and piping of the primary system
2) Zircaloy-4 for cladding of fuel assemblies
3) Incoloy 800, Inconel 690, and Inconel 600 for steam generator tubes
4) High-alloy materials (ferritic stainless steels) of low surface area for internals of the primary system

To fulfill the water chemistry requirements, the primary coolant, which contains boric acid as a neutron absorber, is chemically conditioned by the addition of isotopically pure lithium [^{7}Li] in the form of hydroxide as a solid alkalizing agent and of hydrogen.

In this type of "alkaline" conditioning, the additives lithium [^{7}Li] hydroxide and hydrogen are thermally and radiolytically stable so that no decomposition and conversion products develop. The use of lithium [^{7}Li] hydroxide as a pH control agent is advantageous because ^{7}Li is also formed during power operation from boron in the coolant by the nuclear reaction ^{10}B (n,α) ^{7}Li. If lithium of natural isotopic composition is used, tritium is formed as a result of the nuclear reaction ^{6}Li (n,α) ^{3}H. Thus, isotopically pure lithium [^{7}Li] hydroxide is used to prevent the formation of tritium.

At high temperature, boric acid influences the pH of pure water only slightly because it tends to undergo reversible polycondensation with increasing temperature. For this reason, the pH value at the operational temperatures of the primary coolant is determined virtually exclusively by the pH control agent lithium [^{7}Li] hydroxide. The B: Li ratio can lead to different operational conditions which are described in the following.

In the 1970s there was no concern at all about the B: Li ratio. In the early 1980s several units started to employ the *Coordinated Chemistry* where the lithium concentration is coordinated with that of boron to maintain a pH of 6.9 at operating temperature (see Fig. 47). The upper curve in Figure 47 results when additional 0.2 mg/kg Li are added to the coolant. Such considerations are based on the assumption that the transport of metal oxides (corrosion products) in the primary system depends on the pH value of the coolant at operating temperature and should not be influenced by pH fluctuations.

Figure 47. Schematic of the coordinated chemistry regime (at 300 °C)

Figure 48. Schematic of modified chemistry regime (at 300 °C)

During the 1980s it became evident that the deposition of metallic impurities in ionic and

colloidal forms and in the form of insoluble oxides (called crud) on the core and the reduction of out-of-core radiation fields may be lower at a pH (T) of 7.4. This is in line with the recognition that nickel ferrite is more important than magnetite for materials transport in the coolant. In the 1990s a modified chemistry regime with ≈ 2.0 or 2.2 mg/kg lithium and pH (T) = 7.2 – 7.4 has been adopted by many plants (Fig. 48).

Materials Integrity Considerations. Water chemistry influences both general corrosion and stress corrosion cracking (SCC) of reactor coolant system (RCS) materials. *General corrosion* is an oxidation process which occurs relatively uniformly over a material surface → Corrosion, Chap. 3.1. Some of the corrosion products released from system surfaces form deposits on the fuel elements. Activation products of species present in such deposits (e.g., ^{58}Co, ^{60}Co) and their release, transport, and deposition on out-of-core surfaces leads to increased plant radiation levels that are of particular concern during outages. General corrosion is no fundamental problem for the operation of PWR systems.

In contrast to this, numerous instances of *stress corrosion cracking* → Corrosion, Chap. 3.3.1. have occured. Primary water stress corrosion cracking (PWSCC) of mill-annealed (MA) Alloy 600 steam generator tubes and plugs, for example, has been found. Apparently coolant chemistry is only a second-order effect in the PWSCC process.

In several plants, PWSCC has occurred after one to ten years of plant operation; whereas in other cases, no leaks could be detected after twenty years of operation.

Fuel Integrity Considerations. Nuclear fuel cladding material must possess a unique combination of properties to function as a barrier for radioactivity between the fuel and the reactor coolant. The cladding material must have a low neutron cross-section, high resistance to corrosion, and adequate mechanical properties (see Section 3.1.4).

Zircaloys develop adherent corrosion films when exposed to pure high-temperature water or steam (see Section 3.1.4).

The important environmental factors affecting the corrosion of specific zirconium alloys are: Temperature, radiation, heat flux, quantities of H_2 and O_2 dissolved in the coolant, and coolant additives.

Examples for the influence of environmental factors are shown in Figure 49 (radiation) and Figure 50 (LiOH as coolant addition).

Figure 49. Oxide layer thickness as a function of time
a) PWR fuel rod with constant heat flux $q'' = 75\,W/cm^2$, T_0 340 °C; b) Isothermal inside the PWR; c) Isothermal out-of-file

Figure 50. Effect of LiOH on corrosion of Zircaloy at 350 °C and the lithium content in the grown oxide layer

Another factor may be the corrosion products of non-stoichiometric nickel ferrites, $Ni_xFe_{3-x}O_4$ ($0.4 < x < 0.8$), deposited on fuel surfaces which can lead to increased temperatures of the cladding and increased corrosion rates.

Typical corrosion experience data for zirconium cladding materials from different classes of PWRs are shown in Figure 51. The oxide layer thickness increases with increasing burnup of the fuel rods. Since the discharge burnup has been increased from 10 – 20 MW · d/kg to

currently 50 MW · d/kg, fuel integrity was not a concern in the early days but becomes life limiting in the modern operational conditions. The allowable oxide thickness depends on several factors and is for a uniform oxide layer in the range of 100 μm which is the upper limit value.

Figure 51. Oxide layer thickness plotted against burnup for different PWRs
a) Siemens-KWU KKGg; b) Fragema 1300 MW; c) Siemens-KWU PWR; d) Westinghouse Millstone and North Anna; e) Westinghouse Zion; f) Westinghouse Zorita

The key chemistry parameters requiring control to minimize problems with fuel integrity are discussed below.

Minimization of *dissolved oxygen* concentrations will minimize corrosion of Zircaloy-4. During power operation, the concentrations of oxygen and oxidizing species are controlled by the addition of hydrogen to the reactor coolant and by minimization of oxygen in the makeup water.

Aluminium, calcium, magnesium, and *silica* may be observed intermittently in the reactor coolant as a result of contaminants in the makeup water, the refueling water, or the boric acid. Many oxides and silicates of *aluminum*, *calcium*, and *magnesium* have negative temperature coefficients of solubility, i.e., they will deposit preferentially at the hottest locations in the RCS, namely, on the fuel rods. Likewise, portions of these deposits may be dissolved during reactor cooldown and thus not be detected or only detected in reduced quantity in fuel surveillance programs. Precipitates can densify the porous core deposit and aggravate corrosion of Zircaloy-4, particularly in plants where some boiling occurs. There are no data that suggest that *silica*, in concentrations $< 1000\,\mu g/kg$ and in the absence of the cationic species, will form these deposits, since the silica solubility is > 200 mg/kg under RCS conditions. However, calculations suggest that higher concentrations of silica will precipitate low concentrations of zeolite-forming cations. If aluminum, calcium, or magnesium are present, precipitation/deposition will occur very rapidly and high concentrations of the cations will not likely be detected in the coolant. Therefore, periodic monitoring of the concentrations of these species in reactor makeup streams should be considered.

Silica may be found in high concentrations in the spent fuel and refueling pool waters. During refueling operations, silica contaminates the refueling water via fuel movement through the transfer canal. Removal of silica can be expensive.

In PWRs with Alloy 600-tubed steam generators the concentration of suspended solids in the coolant can be in the range of 50 to 100 μg/kg and they may form deposits on the cladding material. These deposits can lead to increased temperatures of the fuel cladding and thereby to increased corrosion rates. In plants with Alloy 800-tubed steam generators the corrosion product concentration is roughly one order of magnitude lower than in Alloy 600 tubed plants.

Operation below an average pH (T) of 6.9 is not desirable because of the expected increase in the concentration of suspended solids in the RCS, which will lead to heavier crud deposits. At present, almost all plants operate at an average pH (T) > 6.9.

With the currently prevailing rod discharge burnup of 50 – 60 GW · d/MtU, the end-of-life oxide thickness on Zircaloy-4 cladding can reach or exceed 90 – 120 μm in many PWRs, which is the range considered acceptable by most fuel vendors. It is generally agreed that the probability of *lithium* enhancing Zircaloy oxidation increases with oxide thickness, and hence burnup.

The modified chemistry regime is judged to be acceptable for plant operation despite the fact that existing fuel rod oxide data and laboratory test results indicate that switching primary chemistry from the coordinated chemistry to the modified chemistry regime may result in a small increase in cladding oxide thickness at

high burnups. Adverse effects of crud formation will be minimized under these conditions. Likewise, operation at a minimum pH (T) of 6.9 is recommended, even during longer fuel cycles where boron concentrations are high, to minimize crud effects on fuel corrosion.

Radiation Field Control. Shutdown radiation fields can be affected by numerous factors including operational chemistry, plant configuration, materials of construction, and time of operation.

The contribution of the long-lived radionuclides ^{60}Co and ^{58}Co to shutdown radiation can be minimized by reducing the deposition of corrosion products on the surface of fuel assemblies and minimizing the transport of corrosion products between regions of higher and lower temperature. The accumulation of activated corrosion products on out-of-core surfaces is the main cause for buildup of radiation fields that persist after shutdown. Accumulation proceeds via three essential steps. First, corrosion products are released to the coolant from out-of-core surfaces. Second, some of this material is deposited in the core region, where it is activated by the neutron flux. Third, some of the activated material is released from the core and redeposited out-of-core. Primary coolant chemistry influences each of these steps, and its variation during the fuel cycle has an important effect on the accumulated amount of out-of-core radioactivity.

Corrosion rates of out-of-core materials, corrosion product release rates from these materials, solubility of corrosion products, the properties of corrosion product particles suspended in the coolant, and the thermodynamics and kinetics of in-core deposition, release and redeposition out-of-core are partially related to pH. Corrosion products are carried by the primary coolant in two forms: as solids (i.e., metal oxide crud particles) and as dissolved species such as metal ions and their complexes with hydroxyl ions.

The overal process of activity accumulation on out-of-core surfaces involves a complex set of chemical and physical mechanisms. Nevertheless, operation at coolant pH in the range from 7 to 7.4 at 300 °C can be expected to minimize radiation field buildup, with best results at the high end of the range. The most important parameters for activity accumulation are discussed below.

Corrosion Product Release. Corrosion products containing iron, nickel, and cobalt enter the primary system mainly as a result of general corrosion of out-of-core surfaces. This form of corrosion proceeds so slowly in the primary coolant, that it has no measurable effect on the integrity or performance of components, but it is of concern because of its consequences for activation and radioactivity redistribution.

Particulate Transport. Deposits on fuel and corrosion product particles in the primary coolant are visible evidence of corrosion product migration.

Any attempt to understand the behavior of colloids and larger particles must consider the effects of electrical charges that metal oxides acquire when immersed in aqueous solutions. Electrical charges affect the tendency of particles to deposit on another solid surface or to agglomerate with each other. The net charge on metal oxide surfaces is influenced strongly by pH.

Solution Transport. Based on differences in solubility, dissolved corrosion products (e.g., nickel ferrites) can be transported, dissolved, or deposited by the coolant. Solubility of nickel ferrites depends on temperature, pH, and redox potential, all of which vary with position around the nonisothermal loop. The pH at each location may change with time because boron is removed during the fuel cycle, and redox potential may sometimes be altered if there is a change in the concentration of dissolved hydrogen. These differences cause deposits to grow when concentrations of dissolved corrosion products are greater than the solubility limits and to decrease in amount when concentrations are lower.

Plant Experience. Radioactivity accumulation on out-of-core piping and components is mainly affected by corrosion product release, particulate transport, and solution transport. Effects of all three factors should be mitigated by a coolant chemistry with a high-temperature pH between 7 and 7.4. The mitigation should be most effective at the higher end of this pH range.

The effectiveness of the modified coolant chemistry versus the coordinated B/Li chemistry can be shown by comparing the dose rate development of plant I and plant K (see Fig. 52), that differ mainly in the primary coolant chem-

istry. In plant I, with the higher dose rate, coordinated coolant chemistry was preferred with pH (300 °C) = 6.9, whereas in plant K modified coolant chemistry was applied from the very beginning, in this case pH (300 °C) = 7.4. As a consequence of these measures taken, the radiation fields and the average occupational radiation exposures decreased in the Siemens designed PWRs. When a combination of modified coolant chemistry plus substitution of cobalt-based alloys (either partly or fully) is used, an average occupational radiation exposure of less than 50 rem per plant could be achieved.

Chemistry Guidelines. The chemistry guidelines represent the best compromise between the various parameters as discussed in the previous sections. Primary chemistry guideline parameters are divided into two categories:

1) *Control parameters* require strict control due to materials integrity considerations
2) *Diagnostic parameters* assist in interpreting primary coolant chemistry variations, or may affect radiation field buildup, corrosion performance of system material, or fuel integrity.

In addition, action levels are given. They are chemistry limits which are appropriate for protecting system materials, ensuring fuel performance, and controlling radiation buildup. Three action levels have been defined for remedial actions to be taken when parameters are confirmed to be outside the control values. The remedial actions are defined in the individual specifications of the manufacturers. The reactor coolant specifications of Siemens are given as a typical example in Table 26.

Summary and Outlook. The previous sections have described the state-of-the-art in reactor coolant technology for PWR primary systems. However, the current trend toward longer fuel cycles and/or higher enriched fuel has put an additional burden on the optimization of RCS chemistry.

There may be three areas in the near future where changes/modifications have to be expected:

1) Use of enriched boric acid
2) Injection of zinc (depleted in zinc-64)
3) Start-up and shutdown procedures.

Enriched Boric Acid. Natural boron contains $\sim 20\,\%$ ^{10}B that acts as a neutron absorber in the coolant. If enriched fuel is used in the system (e.g., for extended cycles of 18 – 24 month), a higher reactivity binding capacity must be provided by increasing the boron-10 concentration. This can be achieved by increasing the natural boron concentration or by using enriched boric acid.

Injection of zinc (depleted in zinc-64) is carried out to counteract the activity buildup and/or mitigate PWSCC.

Qualification programs for zinc injection are currently ongoing both in the United States and in Germany. The German program is only aimed at radiation field control, whereas in the United States the SCC consideration is included.

Start-up and shutdown periods may be important when considering radiation field control. This may be relevant especially for those units operating with Alloy 690 as steam generator tubing material.

3.1.5.1.2. Secondary System

In pressurized-water reactors, separation of the primary and secondary cycles means that the secondary cycle needs not to meet the safety requirements of the primary cycle, which are necessitated by the interaction of γ and neutron radiaton with water and with the substances contained in it. However, water and steam must not endanger plant operation by material corrosion and its consequences. The requirements on water chemistry include the following:

1) The metal release rates of the structural materials should be minimal
2) The occurrence of localized forms of corrosion should be counteracted
3) The deposition of corrosion products on heat-transfer surfaces should be prevented as much as possible
4) The formation of environments promoting corrosion in the steam generator should be counteracted

Thus, a close connection exists between the choice of materials and water chemistry. The water specifications necessary to fulfill the above-mentioned requirements apply to the following

Figure 52. Dose rate development at main coolant piping of seven Siemens PWRs

Table 26. Specification of the reactor coolant during steady state operation

	NV[a]	Al[b] 1	Al[b] 2	AL[b] 3
Control parameters

materials, which are in contact with water and steam:

1) Incoloy 800, Inconel 690, and Inconel 600 for steam generator tubes
2) Austenitic stainless steels or titanium for condenser pipes
3) Copper alloys for condenser tubes, preheater and moisture-separator-reheater tubing
4) Erosion- and corrosion-resistant materials for parts of the system that transport steam and in which condensation processes occur
5) Unalloyed or low-alloy steels for components and piping of the secondary cycle

The *all-volatile treatment (AVT) method of operation* is used in the secondary cycle (water-steam cycle) to fulfill the demands made on water chemistry. This method of operation is characterized by the fact that chemical conditioning is performed exclusively with the volatile alkalizing agent hydrazine and its thermal decomposition product ammonia. The AVT method can only be used if the secondary system is copper-free.

If the secondary system contains copper alloys amines like morpholine, ethanolamine, and 5-aminopentanol are very often used instead of ammonia. The plant specific selection of a pH control agent depends on:

1) Materials in the secondary cycle system, especially presence of copper alloys
2) Design and use of a condensate-demineralizing system
3) Restrictions regarding the effluents
4) Specific vendor recommendations

An important prerequisite for use of the AVT method of operation is the absence of salts in the secondary cycle to the greatest possible extent, for the following reasons:

Corrosive conditions can arise at the steam generator tubes if salts ingress with the cooling water in the event of condenser leaks. In addition, stagnant steam bubbles can form in certain sectors of the steam generator, e.g., in the deposits of corrosion products on the tube sheet. The ingressed salts are concentrated to saturation in the transition region between the stagnant steam bubbles and the circulating water in the steam generator. Moreover, these salts are hydrolyzed in the steam generator water to produce acid or alkali, depending on the type of salt. These concentration and hydrolysis processes can lead to pH excursions (i.e., strong deviations from the desirable slightly alkaline pH value) and to the formation of aggressive media.

To minimize the entry of salt into the steam generator,

1) Corrosion-resistant materials may be used for condenser tubes;
2) Sensitive methods must be applied to monitor the condenser and locate leaks; and
3) The makeup water for the secondary cycle and the conditioning agent hydrazine must have high purity.

Effective reduction of the ingress of corrosion products into the steam generators can be achieved with a high alkalinity (high pH value) in the secondary cycle. In this way, metal release rates of the structural materials and erosion/corrosion in parts of the system that transport steam can be reduced to a minimum. A prerequisite for the use of the AVT method of operation is the absence of copper alloys in the entire secondary system.

Moreover, reducing water conditions are required to prevent localized corrosion at the tubes of the steam generator. These conditions are guaranteed by conditioning with hydrazine. First, hydrazine binds the residual oxygen:

$$N_2H_4 + O_2 \longrightarrow N_2 + 2\,H_2O$$

Second, the ammonia required to maintain a high pH is formed by thermal decomposition of excess hydrazine:

$$2\,N_2H_4 \longrightarrow 2\,NH_3 + N_2 + H_2$$

Steam Generator Operating Experience (General). Worldwide experience shows that more than 80 % (90 % of those with more than five years operation) of some 250 operating PWRs, including CANDU reactors, have had corrosion or mechanical degradation problems on their steam generators. Such problems often entrain unscheduled or extended outages for preventive and corrective maintenance, which are costly in terms of inspection, repair work, lost power, and personnel radiation protection. Furthermore, the steam generators have been replaced in about 30 PWRs and replacement is planned or underway in more than 20 others.

The size and design of the different types of the predominantly used recirculating steam generators vary widely, and have been changed in the course of time. Nevertheless, the operating conditions remain fairly similar in all cases, leading to virtually identical mechanical loading and chemical environments. The principal characteristics of the steam generators in recent reactors built by Siemens and Framatome are given in Table 27.

The choice of Incoloy 600 was dictated by the following considerations:

1) The 18-10 stainless steels are susceptible to stress corrosion cracking in chloride-containing media. The risk of SCC is increasing, due to the steady increase in size and operating temperature of the generators. Thus, alloys with a high nickel content which are more resistant to this type of attack were considered to be preferable.
2) The thermal expansion coefficient of Alloy 600 is much closer to that of the ferritic steels (used for the shells and tube plates) than that of stainless steel.
3) Satisfactory experience with Alloy 600 in naval reactors suggested that it could also be used in civilian power plants, although size, operating temperature, and thermohydraulic conditions differ significantly.
4) The lower nickel grade Alloy 800 has a lower mechanical strength in the annealed condition. Moreover, the nickel content of Alloy 800 was perceived to be too low to guarantee its corrosion resistance in chloride-containing environments.

Table 27. Operating conditions of recent steam generators

Steam generator	No. of steam generators	Primary temperature	Secondary temperature (pressure)	No. of tubes per steam generator, dimensions
Framatome N4, 1450 MW_e	4	329 °C/292 °C	289 °C/(73 bar)	5599/19.05 × 1.09 mm
Siemens Convoy, 1314 MW_e	4	326 °C/291 °C	280 °C/(64.5 bar)	4118/22 × 1.2 mm

From the late 1960s onwards, many cases of cracking of Alloy 600 occured in the primary medium in regions where the tubes were subjected to the highest mechanical stresses (bends and tube-plate assembly points). In France nowadays, this phenomenon is the major cause of tube plugging and is the principal reason for the replacement of steam generators.

Extensive research work has led to a better understanding of the phenomena involved. It was found that the SCC behavior is extremely sensitive to both the metallurgical structure of the tubes and the testing temperature. The behavior of Alloy 600 tubing could thus be improved significantly in new generators from the early 1980s. An additional vacuum heat treatment at 700 °C at the end of tube manufacture led to a structure with a much higher SCC resistance and reduced the level of residual stresses.

In parallel to this work, an extensive research and development effort was undertaken in a search for new materials. In the early 1980s a recommendation was made to plant constructors to abandon Alloy 600 in new equipment.

Choice of Alloy 800. Reactors with generators equipped with Alloy 800 tubing were developed by Siemens as early as 1972.

The composition of the material employed was modified with respect to the ASTM specifications, in order to improve the corrosion resistance of the tubing and guarantee its long term structural stability.

The alloy is annealed between 960 and 1000 °C. In order to meet the design strength, about 4 % strain is introduced by cold drawing after annealing.

This alloy is also used in the Canadian CANDU power stations commissioned after 1983. In addition, five power stations other than those of the Siemens type have chosen Alloy 800 for replacement steam generators.

Choice of Alloy 690. In virtually all the other steam generators commissioned since 1989 (currently 84 units), the tubing material is Alloy 690, recommended in the early 1980s and adopted in France in 1984. The tubes are given a final heat treatment of a few hours at 715 °C.

Conclusion from Operating Experience. Marked improvements have been made to the steam generators of PWR power plants, and have apparently led to satisfactory solutions. These ameliorations include the overall generator design, the choice of materials for the condenser and reheater sections of the secondary circuit, the water chemistry, the use of either Alloy 800 or Alloy 690 for the tubing, and the tube manufacturing process.

Modifications of the *feedwater circuit* involved the replacement of copper alloys in the condensers and reheaters. If copper is present in the water, only a limited amount of ammonia and hydrazine may be added. This makes it impossible to chemically treat the medium to attain high pH levels that correspond to the specifications for water in the secondary cycle. The use of stainless steels for the exchangers and titanium for the condensers in coastal plants (i.e., seawater-cooled plants) is generally recommended in order to limit the ingress of iron oxides and copper – ammonia complexes into the steam generators.

Currently, the steam generator tubing is best made of Alloy 800, strain hardened by cold drawing (and eventually prestressed by shot peening on the outside surface to improve the SCC resistance in the secondary medium), or Alloy 690, with a final heat treatment at 715 °C to relax residual manufacturing stresses and improve the microstructure.

Since the initial observations of SCC in the *secondary circuit* had been attributed to the presence of sodium hydroxide, extensive testing was carried out in aqueous sodium hydroxide solu-

tions. The results reveal a roughly equivalent behavior for alloys 800 and 690 (Fig. 53), both of which appear to be markedly better than Alloy 600.

Figure 53. Behavior of C-rings [stressed to yield-strength (ASTM STP 425)] in deaerated caustic soda solution at 350 °C
a) Alloy 600 MA; b) Alloy 600 HT 16 h 700 °C; c) Stainless steel 316; d) Alloy 800; e) Alloy 690

The two alloys have different thermal conductivities and thermal expansion coefficients, which are taken into account in plant design and construction.

The stress relieving treatments performed on the welds in the shell have been adapted to account for thermal expansion of the different materials, particularly in the tube-plate.

Water Chemistry Specifications. The complexity of the operational conditions of steam-water cycles and the close connection between design, material, and water chemistry has been described. Instead of discussing all aspects for setting specifications of chemistry, the values defined by Siemens and Framatome for replacement steam generators are given in Tables 28 and 29.

3.1.5.2. Water Chemistry of Boiling Water Reactors

The coolant in the water-steam-cycle of Boiling-Water-Reactors must meet essentially the same requirements as the primary coolant of PWRs. The water chemistry program has to satisfy the following goals in particular:

1) Avoid crack initiation of SCC and/or minimize crack growth of intergranular stress corrosion cracking (IGSCC) and irradiation-assisted stress corrosion cracking (IASCC)
2) Minimize fuel cladding corrosion
3) Minimize radiation field buildup
4) Reduce or minimize general and selective types of corrosion in the BOP systems and components

The concept of BWRs involves radiolytic decomposition of water in the radiation field of the core by forming a steady-state concentration of hydrogen, oxygen, and hydrogen peroxide. The noncondensable gases are, for the most part, transported with the steam out of the reactor pressure vessel. They are largely removed from the cycle through the condenser exhaust and fed to the waste gas system. The interaction between these processes results in widely varying gas concentrations at different points in the water-steam cycle and, consequently, very different oxygen concentrations.

The reactor water contains an equilibrium O_2 concentration of 200 – 300 µL/m^3 and all the hydrogen peroxide formed. This results in a strongly oxidizing environment, so that even water with a very low conductivity can cause SCC in susceptible materials.

In areas of high neutron flux where the environment is most oxidizing, even components constructed with SCC-resistant materials may undergo IASCC. Radiation can change the microchemistry of the materials (radiation-induced segregation), the water chemistry (radiolysis), and the material properties, e.g., stress. Concerns about IASCC are currently increasing, especially IASCC of components that are not readily replaceable. Options to mitigate both IGSCC and IASCC are:

1) Repair and replacement of core internals and of affected piping systems (very costly and time-consuming).
2) Hydrogen addition to the feedwater. This option protects only certain parts of the reactor pressure vessel and the internals. The addition of metal catalysts can improve the situation. This option is currently under development.

Table 28. Chemistry guidelines for replacement steam generators of the Siemens – KWU type (blowdown sample)

	Normal frequency	Frequency	Expected value	Specified value	Action level 1	2	3
Control parameters							
Cation conductivity, µS/cm	continuous		< 0.5	$\leq 1.0^a$	$> 1^a$	$> 2^a$	$> 7^a$
Sodium, µg/kg	semicontinuous		< 10	< 50	> 50	> 100	> 500
Diagnostic parameters							
pH (25 °C)			> 9.0				
SO_4^{2-}		^{b}	^{c}				
Cl^-		^{b}	^{c}				
F^-		^{b}	^{c}				

^{a} Due to total strong anionic species. The theoretical cation conductivity should be calculated and compared to the measured cation conductivity. Any inconsistencies should be investigated. ^{b} To be measured in case of overriding expected values. ^{c} Strong anions to be measured and their concentrations used to check the cationic conductivity specification.

Table 29. Chemistry guidelines for replacement steam generators of the Siemens – KWU type (feedwater sample)

	Normal freqency	Normal value	Expected value	Specified value	Action Level 1	2	3
Control parameters							
pH (25 °C)	3 per week		< 0.5	$\geq 9.3^a$	< 9.3		
Cation conductivity, µS/cm	continuous		< 0.12	$\leq 0.2^b$	> 0.2		
Oxygen, µL/m^3 (ppb)	continuous		< 1	< 5	> 5	> 20	> 100
Diagnostic Prameters							
Hydrazine, mL/m^3 (ppm)		> 0.02					
Cation conductivity, µS/cm		> 5.5					

^{a} as high as possible, compatible with secondary cycle. ^{b} Due to anions of strong acids.

3) Alternatives to hydrogen water chemistry (HWC).

Zircaloy fuel cladding shows an acceptable corrosion behavior under BWR water conditions. However, in the presence of certain impurities, localized effects may occur. In addition, corrosion product deposits can precipitate on the fuel cladding, which may accelerate general corrosion.

Activated corrosion products are responsible for the radiation fields in BWRs. Major parameters influencing buildup of activity are iron and nickel concentrations in the feedwater, higher water conductivity, and concentration of ^{60}Co, ^{58}Co, and Zinc in the reactor water. Corrosion phenomena in the water-steam cycle are not very frequent.

3.1.5.2.1. Stress Corrosion Cracking

The BWR environment is characterized by very pure water (low conductivity) but strongly oxidizing conditions. Actual operating values for conductivity approach the theoretical value of 0.055 µS/cm at 25 °C. An increase in conductivity may endanger all goals of BWR water chemistry. However, conductivity and oxidizing conditions are only two parameters out of several that may influence crack initiation and/or crack growth. These include:

1) Material conditions
2) Mechanical loading
3) Radiation
4) Properties of the protective layers
   - Presence of zinc
   - pH value
5) Environment
   - Conductivity (SO_4^{2-}, Cl^-, CrO_4^{2-}, NO_3^-, crack electrolyte, see below)
   - Corrosion potential (C_{ox}, C_{red}, pH value)

Conductivity. Crack growth rates can increase dramatically when increasing the conductivity (see Fig. 54). Consequently, the *countermeasure* is to keep conductivity in reactor water below 0.1 µS/cm. To this end, maybe improved

cleaning methods must be developed. In addition, it is important to check which kind of impurity causes the increased conductivity. Sulfate contamination as a result of cooling water inleakage, regenerant chemical inleakage, resin ingress or resin decomposition, is most detrimental with respect to environmentally-assisted cracking of BWR materials. Thus, sulfate concentrations should be $< 5\,\mu g/kg$. The second detrimental species is *chloride*. Besides IGSCC of sentitized stainless steels it may also promote transgranular stress corrosion cracking (TGSCC), pitting, and crevice cracking. Especially the combination of chlorides and oxygen is very dangerous for reactor materials. Since chloride accelerates all forms of corrosion its level should be kept below 5 µg/kg during power operation.

Figure 54. Effect of conductivity on IGSCC in-reactor
a) Alloy 182; b) Ferritic steel type 304; c) Alloy 600
NWC = Nitrogen water chemistry; HWC = Hydrogen water chemistry

The next impurity of concern is *chromate* because it can in some cases contribute to more than 50 % to the conductivity at room temperature. In addition, large chromate spikes have been experienced, when switching from hydrogen water chemistry (HWC) to normal water chemistry (NWC).

Finally, the concentrations of *silicia* in the reactor water are 10 to 100 times higher than those of other impurities. However, the impact of silica on IGSCC is considered to be very small.

Other countermeasures against SCC may be understood by using the SCC model of MacDonald shown in Figure 55. According to Figure 55 the crack propagation occurs by an anodic dissolution of the metal at the crack tip. The electrons migrate to the metal surface where they can reduce oxygen or hydrogen peroxide to water. All measures to slow down this mechanism of metal dissolution can be used as countermeasure against SCC. Beside the impurity (conductivity) reduction an increase in the reactor water pH value may be helpful. Such an increase in pH can be achieved by an optimization of the cation: anion ratio of the ion exchange resin in the reactor cleaning systems. Another contribution to a pH increase is the injection of zinc into the BWR coolant. If zinc is integrated into the surface layers, the quality of these layers will be improved and the reduction of O_2 and H_2O_2 thereby slowed down (see Fig. 55).

At present, the best available control parameter for mitigation of SCC in BWRs is an electrochemical corrosion potential (ECP) control. The ECP in normal BWR water chemistry is determined by the production of O_2, H_2O_2, and H_2 and a resulting ECP value between 100 to 250 mV standard hydrogen electrode. The corrosion potential in operating BWRs can be reduced by injecting hydrogen into the reactor feedwater. This results in lower ECP value, the target value for mitigating SCC being < -230 mV. At this level the crack propagation rate should be low enough that no failures will be produced in a 40 years lifetime.

However, the ECP varies significantly around the BWR circuit. Accordingly, H_2 addition to the feedwater will yield a different ECP at various locations. The values at different location can be calculated by an empirical correlation between ECP value and impurities present in the system. In addition, the variations in O_2, H_2O_2 and H_2 around the systems have to be considered. They can be calculated with existing radiolysis models.

In the future, alternatives to hydrogen injection may arise. These include the use of catalysts inside the reactor system or the generation of more isolating protective layers on the metal surfaces. Another possibility may be the use of less volatile reducing agents such as NH_3 or N_2H_4 instead of hydrogen. However, all such alternatives have to be qualified for the use in BWR systems.

3.1.5.2.2. Radiation Fields

Radiation fields during the steady-state operation of BWRs are determined by the nitrogen-16 activity. The major source for personnel expo-

Figure 55. Crack-electrolyte; galvanic coupling effect according to D. D. MacDonald

sure during shutdown is ^{60}Co, which is embedded in the protective layers of the reactor systems.

Nitrogen-16 Radiation Considerations. ^{16}N is produced by the reaction

^{16}O (n, p) ^{16}N

in the core region. Its production cannot be influenced by the chemical environment. However, the behavior of nitrogen-16 in the system, especially its volatility depends on the ECP. Under NWC conditions, the main species of nitrogen are NO_3^- and NO_2^- which are non-volatile. A small fraction, which produces the ^{16}N radiation fields in the main steam area is considered to consist of NO, NO_2, and some NH_3.

Under HWC conditions the nitrogen compounds consist of NH_3 and NH_4^+ which are in equilibrium with one another. Depending on the H_2-concentration the volatility of the nitrogen compounds is increased and thereby the ^{16}N radiation levels. The ^{16}N levels can be increased by a factor of 5 to 6.

Radiation Fields on Out-of-Core Surfaces. The primary source of radiation fields on out-of-core surfaces is ^{60}Co. Most models to describe the transport of activity include the following steps:

1) Crud particles are released to the condensate and feedwater from metal surfaces and subsequently appear in the reactor coolant. In some plants forward-pumped heater drains contribute to the corrosion products and in all plants leakage occurs through the condensate treatment system.
2) Metal ions are also released to the coolant from corroding surfaces in the primary system. Colloidal oxide or hydroxide particles are formed in the coolant when the saturation limit is exceeded.
3) Some interactions between soluble ionic species and crud particles result in adsorption (scavenging) of ionic species on the crud particles suspended in the water.
4) Crud and soluble species deposit on the fuel surface. Some of the loosely attached deposit in the outer layer may be transformed into a tenacious layer on the fuel surface.
5) The deposits on the fuel surface and the in-core structure materials are activated by neutrons. Radioactive species are released from in-core materials by dissolution and wear,

and from fuel surface deposits by erosion and spalling caused by hydraulic shear forces.

6) The radioactive species redistribute into "soluble" and "insoluble" species, depending on the solubililty of the oxide and the concentration of iron crud which acts as a scavenger. Soluble and insoluble radioactive species deposit on out-of-core surfaces by different mechanisms.
7) Formation of double layer surfaces is caused by base metal corrosion and water-borne crud deposition. The oxidation state is changed at the material surfaces (e.g., Fe^{2+} is oxidized to Fe^{3+}) and a small fraction of the corrosion products, both radioactive and nonradioactive, is released mostly from the outer oxidized layer into the coolant.

3.1.5.2.3. Fuel Integrity

Basic consideration regarding fuel integrity are described in Sections 3.1.4 and 3.1.5.1.1. The extent of corrosion and hydriding of Zircaloy in the BWR is determined primarily by the composition of the alloy, the processing history of the Zircaloy cladding, and the presence of water impurities.

In general, the problems with fuel integrity in a BWR environment are smaller than those in the PWR case. This is due to the lower temperature at the oxide metal interface in BWRs.

An anomaly in corrosion behavior, called *nodular corrosion*, can occur in BWRs. This anomaly is characterized by the formation of white pustules, appearing in metallographic cross-sections as lense-shaped oxide deposits with significantly higher thickness than the uniform oxide. Under continued exposure, these pustules grow together to an almost uniform and thick oxide layer. Experience from various BWRs has shown that such corrosion can vary considerably, depending on water chemistry and cladding condition. However, nodular corrosion does not depend on temperature and normally does not limit fuel rod life.

Effects of Specific Coolant Impurities and Additives. The effect of *iron* can be a high crud-loading of the fuel. Operation within the current limits on feedwater iron levels effectively prevents the buildup of iron oxide crud deposits.

A corrosion failure mechanism named crud-induced localized corrosion has been associated with elevated levels of *copper* in BWR feedwater. These failures are characterized by local through-wall corrosion pitting. However, a minimum value for copper to produce this type of failure cannot be given, because the failure depends on the corrosion resistance of the fuel cladding and possible trigger mechanisms.

The addition of *hydrogen* to the feedwater of a BWR effectively mitigates stress corrosion cracking of austenitic materials. In case of moderate H_2 concentrations increased hydrogen pickup need not be worried about. However, hydrogen addition has to be performed with great caution (1) in plants susceptible to crud-induced localized corrosion; (2) in plants operating with cycles > 18 month and a high power density.

Zinc is added to the BWR to adjust a concentration of $5-10\,\mu g/kg$ in the reactor water. When zinc is added, $20-30$ % of the deposited iron oxide in the crud is converted to an iron-zinc spinel. This type of spinel oxide is more adherent to the Zircaloy cladding.

3.1.5.2.4. Chemistry Guidlines

As an example, the present VGB chemistry guidelines for BWRs are given in Table 30.

3.2. Gas-Cooled Graphite-Moderated Reactors

The principal difference between gas-cooled nuclear reactors and other types (e.g., boiling-water and pressurized-water reactors) lies in the coolant and the moderator. The gaseous coolant can be air, carbon dioxide, helium, or another gas. The power densities in the core are low, compared to other reactor types, both because gases exhibit poorer heat-transfer than water or sodium and because graphite is used as moderator. The power density of the THTR-300 (a helium- cooled high-temperature reactor) is $6\,MW_{th}/m^3$, in contrast to the $80\,MW_{th}/m^3$ of water-cooled reactors, which means that the core of a gas-cooled reactor is much larger than that of a water-cooled reactor. This fundamental difference is one of the reasons for the price

Table 30. Present VGB chemistry guidelines for BWRs

	Normal value	Action level 1	2	3
Feedwater				
Conductivity at 25 °C (direct and continuous, µS/cm, measurement at the sampling location)	≤ 0.06	$> 0.07^a$		
Total iron, µg/kg	$\leq 2^b$	> 5		
Total copper, µg/kg	$\leq 0.3^c$	> 0.75		
Oxygen, µg/kg	20 – 200	< 20 and > 200		
Reactor water				
Feedwater Conductivity at 25 °C (direct and continuous, µS/cm, measurement at the sampling location)	≤ 0.15	> 0.25	> 1	> 5
Chloride, µg/kg	≤ 10	> 20	> 100	> 200
Sulfate, µg/kg	≤ 10	> 20	> 100	> 200
Silica, µg/kg	≤ 200			

[a] These are requirements, which may not be fulfilled in single cases. However, they describe the status of the feedwater. [b] Depending on design of the secondary cycle, clean-up procedures and system materials, the parameter "total iron" can have concentrations in the 1 to 5 µg/kg range and this can be tolerated. [c] Depending on the condenser tubing, the parameter "total copper" can have concentrations in 0.2 to 0.5 µg/kg range and this can be tolerated.

advantage of water-cooled reactors over carbon dioxide-cooled reactors. Helium-cooled reactors are competitive with water-cooled reactors.

3.2.1. History

After the discovery of artificial nuclear fission, the first nuclear reactor in the world was built by Fermi in Chicago in 1942. Initially, the reactor power was 0.5 W, later increased to 100 W. Fermi used ca. 46 t of unenriched natural uranium as fuel. About 385 t of graphite served as moderator. The coolant was air.

The first reactor with higher power was also graphite moderated and air cooled. The reactor was commissioned in 1943 in Oak Ridge, Tennessee to generate plutonium for military purposes. The next reactors built in the United States were graphite moderated but water-cooled (Hanford reactors). Thus, in the United States an early changeover to water cooling occurred.

In the United Kingdom gas cooling was retained for plutonium-production because of its greater inherent safety.

3.2.2. Carbon Dioxide-Cooled Reactors

3.2.2.1. Magnox Reactors

The Magnox reactor marked the changeover to peaceful industrial uses of nuclear energy in the United Kingdom and France. The fuel was natural uranium, which meant that only a weak neutron absorber could be used as cladding material (e.g., an aluminum – magnesium alloy). The reactors were named after this Magnox alloy. The choice of coolant was limited to a gas because of (1) the lack of experience with other coolants at the time and (2) the use of natural uranium as fuel, which forced the choice of canning material. The choice of gaseous coolant was further limited by physical, neutron, and chemical properties to either helium or carbon dioxide. Carbon dioxide was chosen because of its more favorable physical properties for this application and because of its low price.

A diagram showing the main components of a gas-cooled reactor (e.g., a Magnox reactor) is given in Figure 56. The design of the various reactors is very different. For example, in French reactors at St. Laurent-des-Eaux, the boilers are below the core, whereas the boilers in British designs are at the side of the core. In general, the French preferred an integral con-

struction whereas the British had a loop design. Figure 57 is a schematic section of the 300-MW_e Magnox station in Oldbury, Great Britain. A section through one of the 500-MW_e Magnox stations in St. Laurent-des-Eaux is shown in Figure 58. Table 31 summarizes the commercial Magnox stations.

3.2.2.2. Advanced Gas-Cooled Reactors

The advanced gas-cooled reactors were built only in Great Britain. The French converted to light-water reactors after the construction of Bugey-1 (see Table 31) for economic reasons. The AGR is a development of the Magnox reactor. The efficiency was improved and costs were lowered by increasing the power density and raising the coolant outlet temperature, as shown in Figure 59. Because of the higher temperatures than in Magnox stations, the fuel elements were canned in stainless steel. This required the use of lightly enriched uranium as a fuel. Further development of the prestressed concrete reactor vessel (PCRV) allowed an increase in primary circuit pressure to > 4 MPa. Steam temperature and pressure were similar to those in coal- or oil fired-stations, thus resulting in high efficiency. A cross-section through the Hinkley Point B advanced gas-cooled reactor is shown in Figure 60. The *core structural components* are made of graphite. Fuel elements are exchanged during operation.

3.2.2.3. Advanced Gas-Cooled Reactor Safety

Because the pressure in the secondary (steam) circuits is always higher than in the primary circuit, carryover of radioactivity into the steam can be ruled out. Maintenance work can be carried out on the secondary circuits without radiation dose problems for the staff. The activity of the primary coolant is very low. In the event of leakage, only a small amount of radioactivity will be released. The core radiation is practically shielded by the PCRV. The primary coolant is in the gaseous state under any operating conditions (in contrast to, e.g., water or sodium that can evaporate or solidify, respectively). Thus, in the event of a reactor incident, no discontinuous change in heat-transfer properties can occur. The amount of excess reactivity in the core is always low because of on-line refueling. If the coolant compressors fail, decay heat can be removed by natural convection. Sufficient cooling water supplies for the steam generators must be available in this case. All important reactor components are designed for redundancy. Because of the good safety properties of the AGR, no containment other than the PCRV is necessary. This means that many components and the auxiliary plant can be maintained or repaired easily during operation, if necessary.

3.2.2.4. Primary Circuit Chemistry

The chemistry of the primary circuit is determined by the Boudouard reaction, in which the core structural component material graphite (which is also the neutron moderator) reacts with the coolant carbon dioxide at high temperature as well as under radiation (thermal and radiolytic corrosion):

$$C + CO_2 \rightleftharpoons 2\,CO$$

Because the graphite core structures are not meant to be replaced, corrosion must be kept to a tolerable level.

Thermal Corrosion. The graphite temperature in a *Magnox reactor* is $< 350\,°C$. The graphite temperature in an *AGR* is kept below 500 °C by an extensive system of coolant channels, although the average gas exit temperature is 650 °C. The coolant channels are shown in Figure 61. Thermal graphite corrosion is very low in both cases.

Figure 61. Diagram showing gas flow in the Hinkley AGR a) Fuel channel; b) Gas circulator; c) 50 % flow cooling shield and graphite; d) Boiler; e) Steam reheater; f) Boiler feed

Radiation-Induced Corrosion. Radiation-induced graphite corrosion by carbon dioxide is observed in both types of reactors. Irradiated carbon dioxide forms, among other ions, a $[CO_2 \cdot CO_2]_n{}^+$ complex with a lifetime of 0.1 μs, which is equivalent to a free path length of about 0.5 µm. The graphite surfaces, including the pores, will be attacked to this depth (when $n = 2$ in the reaction intermediate $[CO_2 \cdot CO_2]_n{}^+$) according to:

$$[CO_2 \cdot CO_2]_2^+ + C \rightarrow 2\,CO + 3\,CO_2$$

The reaction rate increases with carbon dioxide pressure and with radiation dose. This reaction is thus more important for AGRs than for Magnox reactors. The reaction is inhibited by its product carbon monoxide. Hence, the carbon monoxide concentration in Magnox stations is maintained at 1 – 1.5 %. This is achieved by use of a gas purification plant. Much higher concentrations would be necessary for AGRs, which would lead to excessive carbon deposition. For this reason a small amount of methane is injected continually into the primary circuit. Laboratory investigations have shown that methane is an order of magnitude more effective than carbon monoxide in suppressing radiolytic corrosion. The average methane concentration is ca. 500 ppm by

volume. Methane inhibits the corrosion reaction in two ways:

1) Radiolytic disintegration products of methane react with the reactive complexes formed by carbon dioxide radiolysis.
2) During methane radiolysis, finely divided carbon is deposited on the graphite surfaces, especially the pores, which protects the graphite against carbon dioxide oxidation. This protective effect is not completely identical with the protective oxide layer on metals. The oxide layer on metals is not attacked, whereas the deposited carbon is preferentially oxidized and functions as "sacrificial graphite." Methane must, thus, be injected continually.

Part of the methane is oxidized under AGR conditions according to:

$$CH_4 + 3\,CO_2 \rightarrow 4\,CO + 2\,H_2O$$

Most of the water produced is removed continually by special dryers to avoid condensation. This prevents the corrosion of metallic components by water and the increased corrosion of metals by carbon dioxide in the presence of water. The concentration of carbon monoxide must also be limited to avoid carbon deposition. Therefore, carbon monoxide is oxidized to carbon dioxide in a bypass catalyst bed.

/enddocument

Because of the differences in operating parameters among various AGRs–especially the pressure–the optimum carbon monoxide and methane partial pressures differ for each reactor, as do the $CO - CH_4$ ratios. An extensive research program was necessary to determine the optimum concentrations for each reactor.

The radiolytic reactions in the primary circuit yield a variety of mostly *organic compounds* (e.g., ethane, ethylene, propane, acetaldehyde). Table 33 shows the typical concentrations of organic compounds formed by radiolysis in the primary circuit of the Windscale AGR [107]. These concentrations are, however, so low that they do not affect reactor operation.

The principal *radioactive impurity* in the primary circuit is ^{41}Ar, which is formed via a (n, γ) reaction from ^{40}Ar. Argon- 40 is an impurity in the makeup carbon dioxide, or it can result from air leakage. Its very short half-life of 1.8 h means that it is of virtually no importance.

The *fission product concentration* is usually zero and, when it is not zero, it is very low. All fuel elements are monitored and replaced in the event of damage.

A chemical problem observed particularly in AGRs is *carbon deposition* on the fuel elements. The carbon is formed by thermal and radiolytic decomposition of methane:

$$CH_4 \rightarrow 2\,H_2 + C$$

and the reverse Boudouard reaction:

$$2\,CO \rightleftharpoons CO_2 + C$$

Another possible reason for carbon deposition is oil leakage from the primary coolant compressors. Evidence for this is given by the presence of carbonyl sulfide. Compressor oil can contain up to 0.6 % sulfur.

A 0.1-mm-thick carbon layer on the fuel elements can reduce heat transfer so drastically that the elements undergo damage. The carbon monoxide and methane concentrations must be kept within limits at which carbon deposition cannot occur.

Table 33. Typical analysis of a Windscale AGR coolant (760 ppm by volume CH_4/0.25 % CO)

Compound	Amount, ppm by volume
Methane	760
Ethane	32.1
Ethylene	3.75
Propane	9.0
Propene	0.59
Isobutane	1.16
n-Butane	1.04
2,2-Dimethylpropane	0.83
Isopentane	0.73
2,2-Dimethylbutane	8.30

3.2.2.5. Secondary Circuit Chemistry

The steam circuits of the early Magnox stations had circulatory boilers; later, once-through boilers were used. All AGRs are equipped with once-through boilers. The design details do not differ from similar circuits in fossil-fired stations. Water chemistry specifications are unchanged. The pH is controlled by ammonia, hydrazine is used to remove oxygen. Because the pressure in the steam circuits is always higher than in

the primary circuit, the transfer of radioactivity to the secondary circuit in case of a steam leak can be ruled out. The steam is lightly contaminated by small amounts of tritium, which diffuse through the steam generator steel into the steam circuits. However, because of the very low tritium concentration in the primary circuit, the tritium transport rate and, hence, the tritium concentration in the steam circuit are very low.

3.2.2.6. Operating Experience

Operating experience with gas-cooled reactors is generally good. Magnox stations have the reputation of being "nuclear cart horses". However, since about 1970, the gas exit temperatures in the Magnox stations had to be lowered, which has reduced their efficiency. The reason for this corrective measure was carbon dioxide corrosion of mild steels, which was unknown during design of the reactors.

In 1969, broken bolts were discovered initially in British and later also in French reactors. The corrosion was called *breakaway oxidation* because of spalled oxide layers. Corrosion tests before construction of the Magnox stations showed that mild steel forms a protective oxide layer below 450 °C in contact with carbon dioxide. The metal loss rates were so low that no effects were anticipated for the expected 30 years of reactor operation. However, testing stopped too soon. Initially, the protective oxide layer grew with parabolic kinetics. After about 10 000 h of operation the protective oxide layer spalled away from the metal surface. A porous oxide appeared with linear formation kinetics under the protective layer (Fig. 62). Chemical investigation showed that in both cases magnetite was formed according to:

$$3\,Fe + 4\,CO_2 \rightarrow Fe_3O_4 + 4\,CO$$

The breakaway oxide also contained 4 % carbon.

Linear, as opposed to parabolic, kinetics means that the oxide layer is not protective. Oxide growth led to high stresses that caused bolt failures. The effect was amplified by water [108].

Fortunately, the experiments to explain the damage revealed a marked temperature dependence of oxide formation. The porous oxide layer is not formed at $< 360\,°C$. The breakaway problem was solved for operational Magnox stations by lowering the gas exit temperature to 350 °C. In addition, the experiments showed that silicon steels and austenitic steels did not exhibit breakaway oxidation. Austenitic steels form a protective chromium oxide layer on the metal surface. Consequently, austenitic steels were used in those regions of AGRs susceptible to breakaway oxidation.

In the early years of operation, the ferritic parts of some of the steam generators exhibited erosion corrosion, caused by construction features that resulted in unfavorable flow patterns. Numerous shut-downs of the AGRs were caused by problems in the turbine sets (i.e., in the conventional part of the plant).

The AGR was capable of only limited development. The physical characteristics of the core do not allow an increase in power density and consequent reduction in core volume. Gas outlet temperatures are limited by graphite corrosion. Fuel burnup is low. Thus, development of this type of reactor ceased. None of the above limitations applies to the helium-cooled high-temperature reactor.

Interestingly enough, Great Britain– the birthplace of the AGR– did not proceed to the HTR. Only an experimental reactor with no steam turbine was built (Winfrith Dragon Reactor). The successor to the AGR was the internationally tried and tested pressurized-water reactor. However, in the early 1990s, prospects for the pressurized-water reactor are doubtful in the United Kingdom.

3.2.3. Helium-Cooled High-Temperature Reactors

The helium-cooled high-temperature reactor is the next stage of development in the gas-cooled reactor line. The use of helium as coolant and of graphite as the core structural material allows much higher operating temperatures than in AGRs and, hence, higher thermal efficiency. Helium has especially favorable characteristics as a coolant: it is chemically inert, has a high thermal conductivity, and has good neutron physics properties.

The cost of helium has fallen sharply in the last few years because it is a byproduct of the nat-

ural gas industry. The price of helium dropped to less than \$ 5/m^3 (STP) in the latter part of the 1980s. Experience with HTRs has shown that helium consumption only constitutes a small fraction of the operating costs.

Figure 62. Kinetics of oxidation of mild steels in high-pressure carbon dioxide at 400 °C

3.2.3.1. Fuel Elements

Compared to carbon dioxide reactors, the fuel elements in helium- cooled HTRs are completely new. The fuel element consists of small particles of uranium and thorium oxide or uranium and thorium carbide embedded in a graphite matrix. The fuel particles have a diameter of ca. 500 µm. The particles are coated with one porous and one high-density pyrocarbon layer; newer fuel elements are also coated with a silicon carbide layer. The coated particles have excellent retention properties for fission products. The graphite matrix surrounding the coated particles forms an additional barrier to the release of fission products.

The two basic fuel element designs differ with respect to shape: the first is a sphere with a diameter of 6 cm; the second is a hexagonal block, 80 cm high, with a width over flats of 36 cm. Figure 63 shows a schematic of a coated particle and a spherical fuel element. A spherical fuel element contains 20 000 coated particles. The outer layer of the fuel element is fuel free. Hexagonal prismatic fuel elements have a central borehole for ease of handling and smaller channels for cooling of the coated particles and the burnable poison. Apart from these types of fuel element, rod-shaped fuel elements also exist (Dragon Reactor, Peach Bottom Reactor) but are not being developed at present.

Figure 63. HTR fuel element
a) Graphite shell; b) Graphite matrix; c) Coated particle; d) Carbon layers; e) Silicon carbide layer; f) Uranium dioxide kernel

Because of the quasi-homogeneous fuel distribution and the use of *enriched uranium* much higher power densities can be achieved than in AGRs. For example, a typical AGR, the Hartlepool station, has a power density of 2.8 MW_{th}/m^3; several HTRs achieve power densities of 6 – 8 MW_{th}/m^3 (Table 34). The Dragon Reactor's high power density of 14 MW_{th}/m^3 was atypical because it was an experimental reactor. The AVR reactor (Arbeitsgemeinschaft Versuchsreaktor) had a power density of only 2.5 MW_{th}/m^3 to increase its inherent safety (at low power densities, no provision for removal of decay heat is necessary). For the same reason, the power density in the HTR module design is limited to 3.0 MW_{th}/m^3.

The neutron economics of HTR plants are very favorable: Construction of the core from only fuel and graphite means that the core contains no neutron-absorbing materials. Neutron leakage is also small.

Table 34. High-temperature reactors

∗ At outlet of final superheater.

The excellent neutron economy can be exploited in two conversion cycles, the uranium – thorium cycle and the uranium – plutonium cycle. In the former, nonfissile thorium is transformed into the fissile isotope ^{233}U:

$$^{232}Th + n \longrightarrow {}^{233}Th \xrightarrow{\beta^-,\,23.2\,min} {}^{233}Pa \xrightarrow{\beta^-,\,27.4\,d} {}^{233}U$$

The latter cycle is:

$$^{238}U + n \longrightarrow {}^{239}U \xrightarrow{\beta^-,\,23.5\,min} {}^{239}Np \xrightarrow{\beta^-,\,2.3\,d} {}^{239}Pu$$

The uranium – thorium cycle is especially suited to the HTR, whereas the uranium – plutonium cycle can be used more advantageously in the fast breeder reactor.

Because only graphite is used as fuel canning material and only helium as coolant, the core gas exit temperature can be raised to more than 1000 °C. The average gas exit temperature of the AVR in Jülich, Germany was increased to 950 °C in 1974. Lower temperatures were set only for experimental purposes. The change to much higher temperatures is limited by the present state of development of the fuel elements, because the retention capacity of the pyrocarbon and silicon carbide layers for solid fission products decreases at higher temperature. Another limitation is set by the steels used in the heat removal components, such as steam generators and other heat exchangers.

The high gas exit temperature offers more than merely better plant efficiency. The suggestion has been made that HTR power stations should be built as single-circuit units, in which the reactor coolant delivers energy to a gas turbine rather than a steam turbine via a steam circuit. High-temperature helium can be used as a source of heat for chemical processing, e.g., coal gasification (see Section 3.2.3.7).

3.2.3.2. Primary Circuit Materials

Graphite is the key material in an HTR primary circuit. Its most obvious property is its stability at high temperature. The temperature of sublimation is about 3620 K. Graphite is a good moderator because of its low neutron absorption. Graphite displays excellent mechanical properties at high temperature and thus can be used with advantage as a construction material. The coefficient of thermal expansion is much lower than that of metallic materials. This results in lower thermal stresses and favorable behavior during temperature transients. Potential energy

arising from neutron irradiation is stored in the graphite crystal structure at $< 300\,^{\circ}\mathrm{C}$. This stored energy can be released suddenly and can lead to overheating (Wigner energy). To avoid this effect, the graphite temperature even in the coolest parts of the primary circuit is kept above a certain level.

Another effect of irradiation on graphite is a temperature-dependent change in dimension. Below $300\,^{\circ}\mathrm{C}$, graphite shrinks parallel to the direction of the graphite grain and expands perpendicular to it. Above $300\,^{\circ}\mathrm{C}$, graphite shrinks both parallel and perpendicular to the grain direction. The extent of shrinkage depends on the dose. A maximum contraction is reached at $> 10^{22}\,\mathrm{n/cm^2}$, at higher doses, graphite exhibits turnaround and starts to expand. Thus, the linear dimensions may be larger than before irradiation.

Recently developed theories of solid-state physics allow the description, in principle, of the effects caused by neutron irradiation. However, because the graphite components have a very complicated structure, the changes in shape cannot be calculated exactly. For this reason, samples of graphite intended for reactor service are irradiated in material testing reactors. The fast-neutron flux in these test reactors is normally one to two orders of magnitude higher than in power reactors. Thus, changes relevant to power reactors can be investigated in a shorter time. Only those graphites that exhibit disturbance-free operating characteristics during irradiation tests are used in power reactors.

Graphite plays another important role as pyrolitically deposited carbon (→ Carbon, Chap. 4.2.2.). The pyrocarbon layer on the fuel particles has the same function as the metallic canning of fuel rods in other types of reactors. Pyrocarbon, a polycrystalline carbon, is formed by thermal decomposition of hydrocarbons. The particles are coated in a fluidized bed. Acetylene, for example, is used to manufacture the *porous buffer zone* and methane, to produce the *dense surface layer*. *Silicon carbide layers* are produced from silanes by using chemical vapor deposition.

The manufacture of pyrocarbon- coated particles is a complicated technical process, which was optimized as a part of HTR development. The mechanism of pyrolysis has yet to be fully explained. Irradiation of pyrocarbon results in changes in properties. As mentioned above, these changes cannot be calculated; the different types of fuel particles intended for reactor service must be irradiated in material testing reactors.

The most important factors in determining the loads on *metallic components* are the design parameters of the steam circuit. High-alloy austenitic steels are used, as in conventional power stations. The boiler superheaters in the Peach Bottom, Fort St. Vrain, THTR-300, and HTR module designs are manufactured from Incoloy 800 H. In the HTR module, the entire boiler is constructed from Incoloy 800 H.

3.2.3.3. Safety of High-Temperature Reactors

The safety of the high-temperature reactor is characterized by a series of inherent properties, which differentiate it from other reactor types and make it extremely safe.

1) The use of graphite as fuel element cladding and core structural material means that a core meltdown can be ruled out, because a very large difference exists between the normal operating temperature and the maximum tolerable temperature.
2) Temperature transients are slow because of the large thermal capacity of the graphite.
3) If the power density is limited (e.g., in the AVR to $2.5\,\mathrm{MW_{th}/m^3}$ or the HTR module design to $3.0\,\mathrm{MW_{th}/m^3}$), the fuel element does not rise above $1600\,^{\circ}\mathrm{C}$, even if direct cooling fails. Fission product release due to fuel particle bursting occurs at much higher temperatures. Decay heat can be removed solely by conductivity and radiation. In the HTR module design, heat is transferred to the extended surface cooler outside the steel vessel; in the case of AVR, to the steam generator. Figure 64 shows the change of maximum fuel element temperatures in the HTR module design without direct removal of decay heat. To demonstrate these safety properties a loss-of-coolant accident (i.e., failure of the core cooling) was simulated on the AVR. Only a small increase in temperature was observed.
4) Use of helium as coolant is another safety feature. Helium is chemically inert and does

not react with graphite or the metallic core components. Helium cannot be activated, with the exception of trace amounts of ^{3}He. The neutron absorption cross-section is small, so that the core reactivity is not increased in the event of a loss-of-coolant accident.

5) The use of coated particles in the fuel elements results in low contamination levels in the primary circuit and, hence, low radiation doses to operating personnel.
6) An important property of neutron physics is the strongly negative temperature coefficient over the entire temperature range of the reactor. Thus, large power excursions can be ruled out.
7) The chemical reactivity of graphite with air and water at high temperature is, to a certain extent, a disadvantage. The risk of steam entering accidentally via a boiler leak can be limited by construction measures; e.g., the boiler in the HTR module design is displaced to one side below the core. Operating experience also shows that the ingress of foreign substances into the core occurs rarely and is easily controlled.

○ = Atmospheric pressure; ● = Operational pressure

3.2.3.4. Types of High-Temperature Reactors

Various possibilities are available for the layout of the primary circuit in HTRs. Each design has its advantages and disadvantages. Table 34 shows layout data for both existing and planned reactors.

The Dragon Reactor. The Dragon Reactor in the United Kingdom was a joint project of the twelve European OECD nations. It was planned as a research reactor and had no turbine. The 20-MW thermal power was dissipated to the atmosphere via heat exchangers. The first reactor core contained 37 rod-shaped fuel elements. The power density was 14 MW_{th}/m^3, which is atypically high for an HTR. The core was contained in a steel pressure vessel. A graphite annulus was built as a neutron reflector around the core. The six heat exchangers were in external loops. The secondary circuit contained ^{6}Li as a neutron poison.

A major part of the research program involved the investigation of various fuels (e.g., UO_2, PuO_2, UC_2– ThC_2) with different coatings and the release and deposition of fission products. The behavior of nonradioactive impurities in helium was investigated by injection experiments.

The reactor was shut down in 1975 because the contributing nations could not reach agreement about further financing of the project.

Peach Bottom Reactor. The Peach Bottom Reactor in the United States was the first HTR power station. It was built by a consortium of 53 electrical utility companies as part of the reactor demonstration program of the U.S. government. Similar to the Dragon Reactor, its core consisted of fuel pins within an annular graphite reflector. The nuclear portion of the station was placed in a concrete containment. The concrete containment was surrounded by a steel containment, which was filled with nitrogen during operation. During its seven and a half years of operation before its final shutdown in 1974, the reactor achieved, in general, very good operating results. The availability was 37.2 % over the entire period of operation.

The biggest operational problem occurred with the first core. The coated particles of the first fuel element charge had only a single pyrocarbon coating, which in view of the dimensional changes caused by neutron irradiation was not an optimal design. The coating cracked. The improved fuel elements of later cores behaved excellently.

Early in the operating life of the reactor, chloride-induced stress corrosion cracking was

observed in the superheater. The superheater was replaced with Incoloy 800 H tubing.

Fort St. Vrain Reactor. The Fort St. Vrain Reactor design differed in some respects from the experimental Peach Bottom Reactor. The core, boilers, and helium compressors were placed in a prestressed concrete pressure vessel. Its main volume was an upright cylinder 23 m high with a diameter of 9.5 m. A section through the reactor is shown in Figure 65. The core contained 1462 hexagonal fuel element blocks, which were shuffled during the annual reactor shutdown and, depending on burnup, replaced.

The four helium compressors had water labyrinth bearings and were driven by steam turbines, fed by a bleed from the steam circuit.

The reactor went critical for the first time in 1974 and delivered electrical power in 1976. Two years later, it reached 70 % of its nominal full power. The start-up was marked by a series of problems.

During operation, serious temperature fluctuations occurred, caused by flow-induced mechanical vibration of the fuel element blocks. These vibrations occurred whenever the reactor reached more than 70 % of nominal full power. For this reason the reactor was not brought to full power before 1981. The problem was solved by an improvement in the attachment of the fuel element heads. The largest problem was caused by the water labyrinth compressor bearings, which leaked time and again to a greater or lesser degree. The drying out of the core was made more difficult and extended by the fact that the ceramic insulation between the liner and PCRV was wet. This moisture damaged other reactor components. Repair of the damage led to long shutdown periods. Long-term, trouble-free operation was obviously impossible, and the reactor was shut down permanently in 1989. The final determinant of the decision to shut down the reactor was the discovery of hairline cracks in the steam feeds to the compressor drives.

The problems that arose were not typical for HTRs. Together with financial difficulties, however, these technical problems were the reason why the reactor construction company General Atomic gave up various contracts for larger HTRs.

AVR. The AVR has demonstrated the longest and most successful operation of all high-temperature reactors. The differences between the AVR and the aforementioned reactors are the spherical fuel elements and the arrangement of core and steam generator (see Figure 66). The steam generator was placed above the core and very close to it, separated by a slotted roof of graphite – kohlestein (ungraphitized carbon bricks). The helium entered the core at the base, was heated, and flowed through the slots to the steam generator. Cooled helium left the steam generator and flowed around the outside of the core to cool both the core shielding and the pressure vessel. This construction avoided the problems caused by hot gas ducts, especially insulation problems.

The core, the steam generator, and the two helium blowers (compressors) were placed in a double-walled steel pressure vessel.

The ca. 110 000 fuel elements were circulated continually. Spheres that had reached a certain burnup were removed during this process and replaced by fresh fuel elements. 50 fuel elements were replaced per day, on average. The fuel element breakage rate was very low. (Only about one in 20 000 fuel elements was damaged.)

The reactor temperature was controlled by four boron rods in buttresses in the side reflector. The rods that had not been directly driven into the core also served as a reactor shutdown system. Reactor power output was controlled by the compressors.

Only low-alloy ferritic steels were used in the steam generators to avoid the risk of stress corrosion cracking.

The most important operational aim was to demonstrate the smooth operation of a pebble bed high-temperature reactor. The one operational parameter that stood out above all the others was its excellent operational availability. This increased from 53 % in the first full year of operation (1968) to 92 % in 1976. The average availability over the 21 years of operation (December 1967 to December 1988) was 66 %. Many periods of reactor shutdown were caused by the preparation and operation of reactor experiments. The longest shutdown, about one year, arose after massive water ingress in May 1978. About 30 t of water escaped into the shutdown reactor through a small hole in the boiler. What caused the hole is unknown. Most of the water was collected via a valve in the fuel element reloading circuit; the remainder was removed by repeated evacuation and nuclear heating. The experience gained in the incident showed that no damage of any concern arose because of it.

The low coolant activity and, hence, low radioactive deposition led to an extremely low radiation dose to reactor personnel. The fuel elements showed good operational characteristics with very low fission product liberation rates, although in some cases exceptionally high burnups could be obtained.

During the entire period of operation a large number of experiments were carried out. Stress was placed on large-scale fuel tests and investigation of the liberation and deposition of solid fission products. A loss-of-coolant accident was simulated to demonstrate the inherent safety. The "four-rods-jammed" experiment gave two main results. (1) The reactor would shut down quickly because of the negative temperature coefficient even if the shutdown rods could not be activated. (2) The decay heat would give rise to only a small temperature increase in the core. The behavior of chemical (i.e., nonradioactive) impurities under reactor conditions was investigated by numerous experiments in which impurities were injected into the primary circuit.

The AVR was shut down finally at the end of 1988, having fulfilled its aim, to demonstrate the feasibility of operating a pebble bed reac-

tor for 21 years with an extensive experimental program.

THTR-300. All the components in the THTR-300 (Fig. 67) were placed in a PCRV (inside diameter 15.90 m, inside height 15.30 m, wall thickness 4.45 – 5.10 m). All openings were equipped with reinforced pipes. The inner surface of the pressure vessel was fitted with a liner (gastight insulation) with welded pipes through which cooling water flowed. The liner cooling guarded against overheating of the PCRV.

Figure 67. Thorium high-temperature reactor (THTR)
a) Core; b) Steam generator; c) Cooling gas blower; d) Prestressed concrete reactor vessel

Like the AVR, the THTR-300 was a pebble bed reactor: 675 000 spherical fuel elements were circulated continuously and exchanged for fresh elements, if required. As in the case of the AVR the reactor did not have to be shut down to change fuel. To determine when fuel elements should be removed, fuel burnup was determined with a special burnup reactor. Damaged fuel was also removed. The fuel elements contained thorium and highly enriched uranium in a ratio of 10: 1. The absorber elements of the first core contained boron and hafnium. Reactor temperature was controlled by 36 control rods in the reflector. Reactor power was controlled between 40 and 100 % of full power by the compressors. The reactor was shut down by driving 42 shutdown rods into the pebble bed.

Helium was driven down through the core by six electrically driven compressors. Hot helium from the core was collected in a chamber below the core that was equipped with graphite pillars, and then passed upward through one of six steam generators. The helium inventory of 47 000 m^3 (STP) was circulated about twice per minute. The steam generators were once-through boilers with intermediate superheaters. The main cooling water circuit was a closed circuit cooled by a dry cooling tower.

The construction time was greatly exceeded because the reactor was a prototype reactor and the licensing authorities did not possess the proper HTR regulations. During construction, regulatory requirements changed often.

During commissioning, problems with the fuel reloading system occurred, which were solved by slight modification of the equipment. In addition, other problems arose due, for example, to broken bolts in the hot gas duct.

The reactor was not brought up to power again after a planned shutdown in 1988 because agreement could not be reached on the responsibility for financial risks. The decision to shut the reactor down can only be viewed as a political decision of the provincial government. In the second half of the 1980s, public acceptance of nuclear power–after the incidents at Three Mile Island and Chernobyl–was very low.

HTR Module. The HTR module design was developed by Siemens/Interatom and evolved from the AVR design in many aspects, both in reactor philosophy and in component design. The fuel elements are spherical, with a diameter of 6 cm as in the AVR and the THTR-300. Figure 68 shows a section through the reactor and the nuclear heat generation system. The nuclear components and the steam generator are in two separate adjacent steel pressure vessels. Helium is driven downward through the core. It flows with an exit temperature of 700 °C through a horizontal gas duct to the steam generator, rises through the steam generator, and is cooled. Helium then returns through slits around the steam generator tube bundle to the blowers. The cold gas exiting the blower flows in a coaxial pipe around the hot gas duct back into the reactor pressure vessel. It returns to the core via slits in the side reflector. The core diameter is only 3 m. Because of this limited diameter, shut-

down rods that penetrate the pebble bed are not required and the reactor can be shut down with control rods in holes drilled in the side reflectors. A second design limitation is that the fuel element temperature should always be $< 1600\,°C$, even if the active cooling system fails during decay heat removal. The reason is that solid fission products are retained in the coated particles below 1600 °C. This requirement limits the core power density to $3\,MW_{th}/m^3$. To obtain maximum power from the reactor, the core should be as high as possible. The upper limit of 10 m is set by the pressure drop across the core and the problem of xenon swing. The design power of the HTR module is thus limited to $200\,MW_{th}$. For larger stations, a number of HTR modules will be placed together on a site. Auxiliary plants for gas purification, water conditioning, etc., would be common to several module reactors.

In the event of failure of the active cooling in the primary circuit, decay heat is removed simply by conduction and radiation to sheet heat exchangers outside the reactor pressure vessel. Special circuits for decay heat removal are not required. The sheet coolers are also used during normal operation to remove heat leaving the primary circuit.

The displaced layout of steam generator and reactor pressure vessel is advantageous because in the event of steam generator leakage, only a limited amount of water can reach the core. Because the decay heat is removed by the sheet heat exchanger, the steam generator can be decoupled from the reactor if necessary. The displaced layout is also of advantage during periodic reactor inspection.

The HTR module is suited to the generation of process heat for chemical applications. Gas exit temperatures are increased to 950 °C in this case. The many years of operation of the AVR at a gas exit temperature of 950 °C have shown that this is possible with current designs of fuel elements. Various plant concepts are described in Section 3.2.3.7.

3.2.3.5. Chemistry of the Primary Coolant in the High-Temperature Reactor

The primary coolant chemistry in an HTR is determined by the following parameters:

1) The core components and fuel element surface layers are made of graphite. The maximum graphite temperatures are ca. 1100 °C.
2) The coolant is very pure helium.
3) The heat exchangers are the hottest metallic components in the primary circuit. Maximum temperatures at the steam generators in electricity-generating HTR stations are 500 – 550 °C. The process heat units (developmental status in the 1980s) have heat exchanger design temperatures up to 950 °C.

The following *impurities* are generally found in the helium of the primary circuit: H_2O, CO_2, N_2, CO, H_2, CH_4, Ar, noble fission gases, tritium, solid fission products, and dust.

Oxygen cannot be detected above 250 °C because it reacts with, or is chemically adsorbed, by graphite. Nonradioactive impurities are due to small, technically unavoidable air and water

leaks. Hydrogen also diffuses from the steam circuits into the primary circuit. Methane is formed radiochemically.

The concentration of all impurities is in the region of ppm by volume. Table 35 gives the measured concentrations in the AVR, Peach Bottom Reactor, and THTR-300 during normal operations. The values are given in partial pressure (pascal) to allow comparison. The partial pressures were calculated by multiplying the concentration (ppm by volume) by the system pressure.

Table 35. Helium impurities in primary circuit during normal operation (in Pa)

	AVR	Peach Bottom	THTR-300
H_2O	≤ 0.05	< 1.0	≤ 0.05
CO_2	$< 0.5-2.0$	< 0.1	$< 0.4-0.6$
CO	30.0 – 80.0		$< 1.2-1.5$
		1.0	
H_2	5.0 – 10.0	20.0	1.5 – 3.5
CH_4	0.2 – 1.0	2.0	$< 0.4-0.8$
N_2	5.0 – 30.0		< 0.4
		1.0	
Ar	< 0.5		< 0.4
He pressure, MPa	1.1	2.4	4.0

The average concentrations in the Dragon and Fort St. Vrain reactors are not listed in Table 34 because they were high due to external influences. Numerous gas injection experiments into the primary coolant were conducted in the Dragon reactor. In the Fort St. Vrain reactor, numerous leaks occurred from the water labyrinth bearings in the helium compressors.

An important reason for the relatively high concentrations of impurities in the AVR was the presence of carbonate and bicarbonate in the Kohlestein (an ungraphitized carbon material), which decomposed thermally with increasing time of operation. It should be noted that the reactor operation was not influenced by this fact, with the exception of the commissioning phase.

Graphite Corrosion. At the normal operating temperature of 1100 °C the fuel element and core graphite is very reactive toward oxygen, water, and carbon dioxide. Because even trace impurities can lead to unacceptably high corrosion rates, the demands on helium purity are high. In addition, any leakage into the reactor must be avoided as far as possible. Experience so far suggests that both demands can be met. Helium is a byproduct of natural gas production and can be separated from natural gas or from air by liquefaction. Both processes yield a very pure product.

The important graphite corrosion reactions are:

$C + H_2O \rightleftharpoons CO + H_2$	(heterogeneous water gas reaction)
$2C + O_2 \rightleftharpoons 2CO$	
$C + O_2 \rightleftharpoons CO_2$	
$C + CO_2 \rightleftharpoons 2CO$	(Boudouard reaction)
$C + 2H_2 \rightleftharpoons CH_4$	
$CO + H_2O \rightleftharpoons CO_2 + H_2$	(water shift reaction)

The rates of all graphite corrosion reactions are very temperature dependent. The heterogeneous water gas reaction, which is a reaction of special practical importance, is extremely slow at < 500 °C. Thus, an HTR core can be dried without damage at this temperature in case of water leakage. The kinetics of the reaction of graphite with *water* can be divided into three regimes with increasing temperature (Fig. 69):

1) *Chemical regime* (volume reaction). Between 500 and 800 °C the graphite corrodes at the same rate throughout the blocks.
2) *In-pore diffusion regime*. Between 800 and 1200 °C the water concentration decreases with increasing distance from the graphite surface. The corrosion rate decreases in the same direction. The in-pore diffusion regime is the most important reactor corrosion because water leakage occurs at these temperatures.
3) *Mass transport regime*. Above 1200 °C, water reacts so rapidly with graphite that reaction occurs on the graphite surface.

The reaction products hydrogen and carbon monoxide inhibit the graphite – water reaction because of adsorption effects on the graphite surface.

Graphite reacts with *oxygen* under similar conditions much faster than with water. Oxygen is chemically adsorbed on graphite irreversibly above ca. 100 °C. The chemical reaction starts at about 250 °C. The helium must be very pure because of the high chemical reactivity of graphite with oxygen. No air must be allowed to enter the primary circuit during operation. This is, however, unlikely because of the high pressure of the system during operation.

The *Boudouard reaction* (graphite – carbon dioxide) is a secondary reaction of the

graphite – water and graphite – oxygen reactions. Under ca. 700 °C the reaction rate is very low. The reaction is inhibited by carbon monoxide, a reaction product. The rate of reaction of each of the corrosive gases with graphite relative to the rate of the graphite – carbon dioxide reaction (at 800 °C and 10 kPa) may be summarized as follows:

$C + O_2$	1×10^5
$C + H_2O$	3
$C + CO_2$	1

The rate of *radiochemical* corrosion of graphite by hydrogen is several orders of magnitude smaller and depends on reactor power. Experience has shown that this reaction has no practical importance.

In contrast to carbon dioxide-cooled reactors, radiolytic reactions play practically no part in the primary coolant, except for the graphite hydrogen reaction already mentioned.

This was demonstrated by water and carbon dioxide injection experiments in the AVR. The AVR was ideally suited for this purpose because the power could be varied while the outlet temperature was kept constant. No difference was observed in reaction rates at the same temperatures in experiments at half or full power. This does not mean that no radiolytic graphite corrosion by water and carbon dioxide occurs, but that the thermal reactions are much faster and hence determine the reaction rate.

Laboratory investigations have shown that traces of *heavy metals* (e.g., iron) and *fission products* (Ca, Ba, Sr) catalyze all gas – graphite reactions. Operating experience is that iron occurs in the primary circuit as the oxide and is ineffective as a catalyst. The fission product concentrations on the graphite surfaces are so small that postirradiation examination of fuel elements, with a few exceptions, shows no increased graphite corrosion.

Carbon Transport. During the cooling of helium in the primary circuit the aforementioned graphite corrosion reactions can run in the reverse direction on the surface of metal catalysts (e.g., on the metallic parts of the steam generators). This gives rise to carbon deposition. In addition, carbon is formed by decomposition of the methane present in the gas space. This carbon, together with fuel wear, gives rise to a low concentration of dust in the primary circuit. Dust concentrations measured in various HTRs are between ca. 1 and 10 μg/m^3 (STP). Dust collects in various parts of the primary circuit. The dust is of radiological importance because it is the transport medium around the circuit for various solid fission products. Gas – graphite reactions are not influenced by the dust. Carburization of steam generator steels does not occur because of the relatively low temperature.

Gas – Metal Reactions. Carburization and other chemical reactions of trace gases with metallic materials occur, however, if an HTR is used to generate process heat. Numerous experiments have shown that trace contaminants in helium can give rise to corrosion (H_2O, CO_2), carburization (CO, CH_4), and decarburization. The type of process depends on the gas composition, the metal used, and the temperature.

Long-term experiments show that chromium, in particular, determines the alloy behavior [109]. The chromium content of almost all suitable alloys is at least 20 wt %.

Chromium reacts with *water* to yield the oxide:

$$2\,Cr + 3\,H_2O \rightarrow Cr_2O_3 + 3\,H_2$$

Chromium carbides are *decarburized*, e.g.,

$$Cr_{23}C_6 + 6\,H_2O \rightarrow 23\,Cr + 6\,CO + 6\,H_2$$

Carburization reactions with carbon monoxide and methane are

$$9\,Cr + 3\,CO \rightarrow Cr_7C_3 + Cr_2O_3$$

$$7\,Cr + 3\,CH_4 \rightarrow Cr_7C_3 + 6\,H_2$$

The gas composition can be adjusted so that a stable protective chromium oxide layer forms. A minimum partial pressure of carbon monoxide in the primary coolant and a certain $CO - H_2$ ratio are essential. Operating experience with HTRs shows that because of small unavoidable air and water leaks, and because of desorption reactions from graphite, low concentrations of impurities are always present in the primary circuit. The conditions for the stability of the protective oxide layer (a certain amount of CO and H_2O)

are, thus generally fulfilled during normal operation. If the concentration of carbon monoxide is too low during normal operation, the primary coolant can be dosed with carbon monoxide.

If a protective oxide layer is not present, chromium carbides can be formed at $< 850\,°C$. At very high carbon monoxide concentrations, carbon deposition is possible at $\leq 650\,°C$. Long-term experience with the AVR showed, however, that despite continually high carbon monoxide concentrations and the use of unalloyed steels, only a small amount of carbon deposition was observed.

Figure 69. Temperature regimes of graphite corrosion with water vapor
a) Chemical regime; b) In-pore diffusion regime; c) Mass transport regime

Helium Purification Plant. The helium purification plant has the following functions:

1) Removal of the corrosive impurities water and carbon dioxide
2) Limitation of carbon monoxide and methane to minimize dust formation
3) Removal of tritium to reduce the amount that diffuses into the secondary circuits (hydrogen is retained along with tritium)
4) Removal of nitrogen to minimize ^{14}C formation
5) Removal of radioactive noble gases. However, only the concentrations of the long-lived noble gases are decreased, e.g., ^{85}Kr, (half-life 10.8 a) and ^{133}Xe (half-life 5.3 d).

Only small amounts of graphite dust can be removed because graphite is deposited in the circuit and does not reach the helium purification plant. The dust filter upstream serves to protect the helium purification plant.

The various steps in purification are adsorption processes on solid adsorbents. Gas scrubbing, found in industrial gas purification, is not used. Gas purification occurs in a series of steps. First, hydrogen and carbon monoxide are catalytically oxidized to water and carbon dioxide on a copper oxide bed at ca. 300 °C. Second, carbon dioxide and water are adsorbed on a molecular sieve. Methane, nitrogen, argon, and both active and inactive xenon and krypton isotopes are adsorbed on activated charcoal at liquid nitrogen temperature. On the AVR, hydrogen and carbon monoxide are converted with oxygen on a platinum catalyst bed. This process has functioned well.

A helium purification plant consists normally of two parallel streams. One of these is on-line, while the other is regenerated. For economic reasons the plant is designed as a bypass unit.

Fission and Activation Products. Although, in principle, the same fission and activation products occur in high-temperature reactors and light-water reactors, the differences between their release and their behavior are marked. The principal reason can be found in the new HTR fuel concept in which graphite is used as a canning material instead of metal. A second reason is the fine fuel distribution in coated particles.

The gaseous fission products, (e.g., noble fission gases and tritium) are almost completely retained under normal conditions. The retention capability for solid fission products is also very good. If no broken particles are present, fission product release is caused almost exclusively by the uranium contamination that remains outside the coating during fuel fabrication. Depending on the type of fuel, the average uranium contamination is between 10^{-4} and 10^{-5} (ratio of fissile material outside the fuel particles to that inside). This value is one of the most important parameters in fuel element fabrication.

In addition to the coating, the graphite matrix and the fuel-free zone form an additional barrier against fission product release. Depending on their half-lives, a large proportion of *fission product gases* decay during diffusion through the pores of the graphite. The graphite of the core structural components and of the fuel element surfaces forms a very effective sink for all *solid fission products* due to its large adsorptive capacity. The concentrations of solid fission and activation products are so low that they can be

determined only after a preconcentration step. The majority of *tritium* is chemisorbed on the graphite of the fuel elements and the core structural components.

Table 36 shows typical noble gas concentrations measured on the AVR at an average gas exit temperature of 950 °C in September 1983. The R/B value is normally given, in addition to the absolute concentration. The R/B is a dimensionless number–the ratio of the amount of activity released R to the activity formed B. The R/B for ^{85}Kr cannot be measured because it does not reach equilibrium in the primary coolant. ^{85}Kr has a long half-life and accumulates in the fuel particles. Therefore, the ^{85}Kr concentration in the coolant is an important parameter because a marked increase in concentration is an indication of broken fuel particles. In case of air ingress ^{41}Ar is detected in the coolant.

Table 36. Noble gas fission products in the AVR primary circuit (950 °C, 1983)

Noble gas	Half-life	Concentration, Bq/m^3	R/B
^{85m}Kr	4.48 h	7.88×10^7	6.2×10^{-6}
^{85}Kr	10.76 a	0.2×10^7	
^{87}Kr	76.3 min	11.33×10^7	4.4×10^{-6}
^{88}Kr	2.8 h	11.40×10^7	3.6×10^{-6}
^{89}Kr	3.18 min	4.87×10^7	1.2×10^{-6}
^{90}Kr	32.2 s	1.27×10^7	0.3×10^{-6}
^{91}Kr	8.6 s	0.05×10^7	0.02×10^{-6}
^{133}Xe	5.29 d	6.80×10^7	4.3×10^{-6}
^{135}Xe	9.17 h	12.53×10^7	2.6×10^{-6}
^{135m}Xe	15.3 min	2.22×10^7	1.4×10^{-6}
^{137}Xe	3.8 min	4.11×10^7	0.8×10^{-6}
^{138}Xe	14.1 min	2.08×10^7	0.4×10^{-6}
^{139}Xe	39.7 s	0.69×10^7	0.2×10^{-6}

The R/B is a useful method for comparing different HTRs. The given AVR values are of the same order of magnitude as in other reactors.

The fission product concentration in the gaseous coolant is temperature dependent. Quantitative relationships can be investigated in the AVR because the average core gas exit temperature can be altered at full power between 770 and 950 °C. The temperature dependence of the release of gaseous fission products is weak, in contrast to that found for solid fission products.

The concentration of solid fission products in the coolant is an order of magnitude lower than that of gaseous fission products. One reason for this, the deposition on graphite surfaces in the primary circuit, was mentioned above. Deposition also leads to a concentration difference for most solid fission products between the hot and cold regions of the circuit. The concentration in the hotter regions is higher. Table 37 gives the fission product concentrations determined on the AVR at a gas exit temperature of 950 °C in 1984. The activities were determined by preconcentration of 2700 m^3 of helium over a two-week period. Because of the long preconcentration time, both concentration minima and maxima were smoothed out.

Table 37. Solid fission products in the primary circuit of the AVR at 950 °C (1984)

Isotope	Half-life	Concentration in hot gas, Bq/m^3 (STP)	Concentration in cold gas, Bq/m^3 (STP)
^{90}Sr	28.5 a	70	45
^{110m}Ag	250.4 d	350	50
^{131}I	8.04 d	320	17
^{134}Cs	2.06 a	300	30
^{137}Cs	30.1 a	555	92

Activation products, such as ^{60}Co, ^{59}Fe, ^{51}Cr, ^{54}Mn, and ^{46}Sc (scandium is an occasional impurity in graphite), are found in the primary circuit in addition to solid fission products. Their concentrations are in the same range as the fission products.

Tritium. Tritium plays a special role in all gas-cooled reactors because it is the only isotope that can diffuse into the steam circuits under all operational conditions. The tritium in the primary coolant is principally an activation product of ^{3}He, ^{6}Li and ^{10}B. Tritium produced by fission is almost completely retained in the coated particles, as shown by postirradiation examinations.

Tritiated hydrogen (HT) makes up more than 90 % of the gas-phase tritium. Tritium is also found as CH_3T and HTO. The majority of tritium is chemically adsorbed on the graphite components in the primary circuit and can be released by exchange reaction with nonradioactive hydrogen. (This exchange explains the observation that the concentrations of nonradioactive and tritiated hydrogen in the primary coolant are linked). Tritium in the primary coolant is removed, together with nonradioactive hydrogen, in the helium purification plant. A small proportion diffuses as tritium atoms through the boilers into the steam circuits. There it forms tritiated water. The gas- and steam-side oxide films form

an important permeation barrier. The steam-side oxide layer can be improved by oxygen treatment of the feedwater, if certain conditions are fulfilled.

Tritium concentration in the steam circuit is low. The measured concentration in the steam circuits of the AVR and THTR-300 was 10^4–10^5 Bq/kg.

3.2.3.6. Steam Circuits

Only once-through boilers have been used in HTRs (an exception is the Dragon Reactor, which did not have any turbine circuit). The steam quality is similar to that in modern fossil-fired power stations. Thus, in HTRs the same impurities can be expected as in fossil-fired power stations. These impurities arise from corrosion, condenser leakage, or breakthrough in the feedwater conditioning plants. Thus, chemical impurity guidelines for the once-through boilers in fossil-fired power stations can be used. In general, the steam circuits are alkaline conditioned. Combined feedwater conditioning is used on the AVR. In combined conditioning the feedwater is dosed with oxygen. The oxygen serves as a corrosion inhibitor.

If the steam generator lies in the neutron flux from the core, radioactive corrosion products (e.g., ^{59}Fe, ^{60}Co, ^{65}Zn) are found in the secondary circuits. This was true of the AVR and, to a lesser extent, the THTR-300. Because the pressure in the steam circuits is always much higher than in the primary circuit, fission products cannot pass into the steam circuits.

3.2.3.7. Nuclear Process Heat

The HTR need not be used only to generate electricity; it is also a versatile heat source. The suitability of the HTR pebble bed reactor as a source of process heat was demonstrated in 1974, when the gas exit temperature of the AVR was increased to 950 °C. Because of its inherent safety, an HTR unit can be built as part of a chemical plant or other industrial plant without special protective measures. Coal gasification was investigated as part of a series of studies in the

Figure 71. Schematic of the coolant and power conversion systems

Projekt Nukleare Prozeßwärme (nuclear process heat project). Components were tested for all applications, and suitable materials were chosen in a material testing program.

The following areas of application were investigated among others:

Coal gasification by hydrogenation
Steam reforming of coal
District heating with combined heat and power generation
Process steam for the chemical industry
Desalination of seawater
Tertiary oil production
Natural gas reforming

Coal gasification yields substitute natural gas (SNG) or synthesis gas. The latter is a starting material in the industrial production of hydrogen, methanol, and gasoline, among others.

3.3. Graphite-Moderated, Light-Water-Cooled, Pressure Tube Reactors

The graphite-moderated, light-water-cooled, pressure tube reactor has a unique design, which has been developed and constructed only in the former Soviet Union. With a total of 15 units connected to the grid by the end of 1989 (see Table 38), this type of reactor constitutes an important part of electrical power production in the former Soviet Union.

Table 38. Soviet graphite-moderated, light-water-cooled reactors connected to the grid ∗

Reactor	Gross capacity, MW_e	Year of grid connection	Year of commercial operation
Beloyarsky-2	160	1967	1969
Chernobyl-1	1000	1977	1978
Chernobyl-2	1000	1978	1979

∗ Data from Dec. 31, 1989.

The graphite-moderated, light-water-cooled, pressure tube reactor differs in essential design characteristics from other reactors. The first unit

of this type, Beloyarsky-1 (capacity 100 MW_e) began commercial operation in 1964; the second, Beloyarsky-2 with a capacity of 200 MW_e, in 1967. After these two demonstration plants, the former Soviet Union began to construct full-scale 1000-MW_e units (Soviet abbreviation: RBMK-1000). The first RBMK-1000 was connected to the grid at the Leningrad atomic power station in 1973. By the end of 1989, 13 RBMK-1000 were operating. In 1985, the first of two larger units of this reactor type with a capacity of 1500 MW_e (RBMK-1500) began commercial operation at Ignalina. The design and the core size of the RBMK-1500 are similar to those of the RBMK-1000, but its fuel power density is 50 % higher.

Significant differences in design exist between the first-generation RBMK-1000 units, such as Leningrad 1 to 4, and the more recent second-generation units, such as Chernobyl 3 and 4 or Smolensk 1 and 2. Because more information is available on second-generation units, these RBMK-1000 units are described in the following sections.

3.3.1. General Design Characteristics

The RBMK-1000 reactors are constructed as twin units. Auxiliary building, switchyard building, and turbine building are common to both units. The two reactor buildings and the auxiliary building located between them are integrated into one large building. Parallel to this large building is the turbine hall with the four turbine generators (two for each unit). The reactor and auxiliary building are connected by the switchyard building to the turbine hall. The switchyard building contains separate control rooms, switchyards, cable rooms, and venting systems for the two reactor units (Fig. 70).

The RBMK-1000 reactor is a vertical pressure tube, graphite-moderated, boiling-water-cooled reactor with online refueling. The uranium dioxide fuel is located in 1661 vertical pressure tubes. The reactor coolant system consists of two independent loops supplying coolant to separate halves of the core (Fig. 71). Each loop contains two steam separators (b) and four reactor coolant pumps (c) (three in operation and one on standby under normal conditions).

Coolant enters the pressure tubes from the bottom at 270 °C. In flowing through the pressure tubes the coolant is heated and partially evaporates. Coolant pressure and temperature at the core outlet are 7 MPa and 284 °C. The average core outlet fraction of steam is 14.5 % at full power. Steam and water are separated in the separators (b) of the corresponding loop. Reactor coolant pumps (c) supply the water back to the headers, which distribute it via subheaders to the individual pressure tubes of the reactor core (a). Steam is fed to the two turbine generators (f)–with an output of 500 MW_e each–via steam lines connected by headers. After leaving the low-pressure turbine, steam condenses in the main condenser (g). The condensate is pumped back to the steam separators by the condensate (h, i) and feedwater pumps (d). It enters the steam separators at 165 °C and mixes with water from the core outlet to provide recirculation water of 270 °C. Coolant flow through the pressure tubes is adjusted by manually operated flow control valves in the coolant supply lines of the individual pressure tubes. In addition, the overall core coolant flow can be adjusted within a certain range by control valves in the discharge lines of the reactor coolant pumps. The main technical data of RBMK-1000 reactors may be summarized as follows:

General design characteristics

Thermal capacity	3200 MW_{th}
Gross electrical capacity	1000 MW_e
Net electrical capacity	925 MW_e
Total reactor coolant flow rate	37 600 t/h
Operating pressure	7 MPa
Core outlet temperature	284 °C
Core inlet temperature	270 °C
Total steam flow rate	5780 t/h
Feedwater inlet temperature to steam separators	165 °C

Core description

Height/diameter	7 m/11.8 m
Number of fuel channels	1661
Lattice spacing	250 mm × 250 mm
Moderator material	graphite
Moderator mass	1700 t
Maximum allowable moderator temperature	750 °C
Reflector dimensions	
Top and bottom	0.5 m
Sides	0.88 m

Fuel

Number of fuel elements per fuel channel	2, connected in series
Number of fuel rods per fuel element	18
Fuel material	UO_2
Total uranium mass	190 t
Enrichment	2 wt % ^{235}U
Maximum fuel burnup	20 000 MW · d/t
Cladding material	Zr – 1 % Nb
Active core height	6.9 m
Average rod power	150 W/cm

Control rods

Number of control rod assemblies	211
Cladding material	aluminum
Neutron absorption material	B_4C
Control rod spacing	500 mm × 500 mm
Control rod travel	6.25 m
Insertion velocity	
Control mode	0.20 m/s
Shutdown mode	0.40 m/s

Fuel channel

Number	1661
Length of pressure tube	
Total	22 m
Below core zone	5 m (stainless steel)
Core zone	8 m (Zr – 2.5 % Nb)
Above core zone	9 m (stainless steel)
Pressure tube outer diameter	88 mm
Pressure tube wall thickness	4 mm
Average tube power	1.89 MW
Maximum tube power	3.25 MW

Reactor coolant recirculation system

Independent flow loops	2
Steam separators	4 total, 2 per loop
Pumps	8 total (6 operating, 2 standby)
Pump dynamic head	1.96 MPa
Pump capacity	5500 – 12 000 m^3/h

Steam secondary system

Steam collector	primary system steam separators
Number of steam separators	4 total, 2 per loop
Steam separator	
Inner diameter × length	2.6 m × 30.984 m
Power generation	1000 MW_e
Turbine generators	2500 MW_e each
Feedwater inlet temperature to steam separators	165 °C

3.3.2. Reactor Core

The reactor core (Fig. 72) has the shape of a cylinder 11.8 m in diameter and 7 m high. It consists of graphite blocks with a cross-section of 250 mm × 250 mm and a height of 600 mm. The graphite blocks are stacked together. They form the moderator with a total mass of 1700 t. In addition, top and bottom graphite reflectors, each 500 mm high, and a radial graphite reflector 880 mm thick yield a total graphite stack 8 m in height and 13.8 m in diameter. The *pressure tubes* that contain the fuel elements and the *guide tubes* for the absorber rods are located in central vertical holes of the graphite blocks, thus forming a lattice with a pitch of 250 mm. Each graphite block has such a hole except for those blocks that form the radial reflector. A total of 1661 fuel channels and 211 channels for absorber rods can be found.

The *graphite stack* is surrounded by a leak-tight vessel (e) formed by a cylindrical steel shell together with the upper (b) and lower biological shields (h). A gas mixture of 80 % helium and 20 % nitrogen is fed into this vessel to provide a medium for heat transfer from the graphite stack to the coolant channels. The gas mixture is monitored for moisture to detect any leakage from the channels.

The *fuel* and *absorber rod channels* penetrate the upper and lower biological shields. They are connected above and below the reactor core to the corresponding loops of the reactor coolant system and the absorber rod cooling system, respectively. The drives of the absorber rods are located above the core and below the removable operating floor shield structure.

Fuel Channels. A simplified cross-section of a fuel channel is shown in Figure 73. The fuel channels contain *fuel assemblies* consisting of two fuel elements connected to a central support tube. The *fuel elements* are cylindrical 18-rod clusters each 3.644 m long. In the past, 1.8 and 2 % enriched uranium dioxide fuel in the form of sintered uranium dioxide pellets had been used. After the Chernobyl accident the enrichment of the fuel was increased to 2.4 %. The total mass of the fuel is 190 t. For neutron economy the fuel rod cladding tubes and the section of the pressure tubes in the core region are fabricated of zirconium – niobium alloys (Zr – 1 % Nb and Zr – 2.5 % Nb, respectively). Above and below

Figure 72. Cross-section of reactor cavity

the core the pressure tubes consist of stainless steel that is diffusion welded to the zirconium section. The flow rate of the coolant in an individual fuel channel can be adjusted over a certain range by a manual control valve in the inlet section of the fuel channel.

The fuel channels are designed to allow *refueling during power operation*. For refueling the refueling machine is lowered over the outside of a fuel channel. After establishing a leaktight connection between fueling machine and fuel channel the plug on top of the fuel channel is unsealed. The plug and the spent fuel assembly are lifted from the fuel channel into the fueling machine. The fresh fuel assembly and the plug are then inserted into the fuel channel. Finally, the plug is sealed and the fueling machine is removed from the fuel channel. Cooling water is pumped from the fueling machine into the fuel channel during refueling to cool the discharged fuel assembly.

The 211 absorber rods that move in special channels in the graphite stack are designed for control of overall reactor power and power density, as well as for reactor shutdown. Cooling of these channels and the absorber rods is provided by the control rod cooling system.

3.3.3. Reactor Physics

The physics of the RBMK reactor is characterized by its graphite moderator, the large size of the reactor core, and the large core load of enriched uranium fuel. In contrast to PWRs and BWRs in which coolant and moderator are indentical, the RBMK reactor uses water as coolant and graphite as moderator. This has an important effect on the neutron characteristics of the RBMK reactor. Because of the large graphite – fuel ratio, the graphite moderator produces a sufficient amount of thermal neutrons under most operating conditions. In such a design the neutron moderator function of the coolant water is small, whereas its neutron absorber function plays an important role. Therefore, if the coolant void fraction increases, the number of neutrons absorbed by the water decreases and thus the number of neutrons available for fission increases, resulting in an increase of reactor power.

The dependence of the change of reactivity on a change of coolant void fraction is characterized by the *coolant void coefficient*. The sign and magnitude of this coefficient are functions of control rod position, fuel enrichment, fuel burnup, and supplemental absorber loading. For the RBMK reactor the coolant void coefficient is positive under most operating conditions; it increases with increasing fuel burnup or when the absorber rods are withdrawn from the core. Two other important reactivity feedback coefficients are the *graphite temperature coefficient* and the *fuel temperature coefficient*. The graphite temperature coefficient and the fuel temperature coefficient (Doppler coefficient) characterize the dependence of the reactivity on the temperature of the graphite stack and the fuel temperature, respectively. The graphite temperature coefficient is also positive. The fuel temperature coefficient is the only coefficient that is always negative.

For RBMK-type reactors, incidents or accidents that lead to an increase in coolant void fraction may result in an uncontrolled power increase, if they are not limited in time by the control system or reactor shutdown, respectively. Therefore the design must ensure that the reactor shutdown system is actuated and becomes effective in a sufficiently short time under all circumstances. Examples of incidents or accidents leading to an increase of the coolant void fraction are loss-of-coolant accidents, depressurization of the reactor coolant system, flow reduction in the reactor coolant system, or an increase of core inlet temperature.

The coolant void fraction depends on the reactor power. It is small at low power and increases to 14.5 % at full power. Thus, the total possible amount of changes in coolant void fraction and neutron flux is larger at low power compared to full power. In addition the fuel temperature is low at low reactor power; that is, the stabilizing effect of the fuel temperature (negative temperature coefficient) is less effective than at full power. As a consequence, the RBMK reactor is more sensitive to power transients at low reactor power than at full power. To prevent unacceptable power transients at low reactor power the procedures require immediate manual reactor shutdown by the operators if reactor power drops below 20 %.

3.3.4. Instrumentation and Control

The reactor is widely instrumented to guarantee economic and safe operation. The monitoring and control system is composed of two subsystems: the control and protection system and the reactor process monitoring system (SKALA).

The *reactor instrumentation* consists of:

1) Ionization chambers in the reflector region for overall power control;
2) Iission chambers in the reflector and in the core region for reactor start-up and local automatic control;
3) β - Emission sensors in the core region for measurement of axial and radial neutron flux distribution;
4) Thermocouples for monitoring the temperature of the graphite stack;
5) γ-Spectrometer probes for measuring the activity of the steam – water mixture in the core outlet pipes (detection of fuel cladding failure);
6) Measurement of relative humidity and temperature of the helium – nitrogen mixture in the reactor vessel (monitoring the integrity of the fuel channels); and
7) Measurement of the coolant flow rate in the process and control channels.

Control and Protection System. Regulation of reactor power and power density, as well as emergency protection, is performed by the control and protection system. Two independent sets of controllers are used for power regulation of the reactor: *overall power control* and *local automatic power control*. The overall power controller has three modes of operation: manual, automatic, and emergency control. The local power controller operates in two modes: automatic and emergency control.

Power control and emergency shutdown of the reactor are provided by 211 control rods (absorbing rods), which are grouped as follows:

115 manual control rods
12 control rods for overall power control
12 control rods for local automatic power control
24 emergency control rods
24 local emergency control rods
24 short absorbing rods.

Overall Power Control. The overall power controller consists of three identical regulators. Each regulator operates with a set of four control rods that are distributed symmetrically over the reactor core. One of these regulators provides power control for low power (0.5 – 10 %); the remaining two, for the range of 5 – 100 % of full power (one regulator in operation and one on standby).

Local Automatic Power Control. Local automatic power control is provided by 12 control rods with independent regulators. Local power control is the preferred system for power regulation in the range of 10 – 100 % of full power because of its ability to smooth out radial – azimuthal power distortions during transitional states.

Manual Power Control. Manual control of reactor power and control of excess reactivity can be performed by four groups of control rods (one peripheral group plus three centrally located, regularly intermixed lattices of control rods).

Figure 74. Control rod
a) Absorber section; b) Displacer section; c) Belt; d) Aluminum alloy cladding; e) Boron carbide; f) Void for coolant passage; g) Graphite; h) Aluminum alloy cladding

Control Rods. The control rods can be subdivided into 187 control rods of full length and 24 short absorbing rods of half length. The short absorbing rods are used only for the control of the axial power distribution in the lower part of the reactor core. The control rods (Fig. 74) are composed of six absorbing sections (a), each about 1 m long and containing boron carbide as absorbing material enclosed in sealed annular aluminum alloy elements (short absorbing rods contain three absorbing sections only). Except for the rods for overall power control, all control rods are equipped with five displacer sections (b) of 1-m length each at the bottom (at the top for short absorbing rods). The displacers are filled with graphite to improve neutron efficiency in the reactor when the control rods are partially withdrawn from the core (the strongly neutron absorbing water in the control rod channels is then replaced by the graphite of the displacer elements). If a control rod is fully withdrawn from the reactor core, a core section of 1 m on either end of the displacer element is filled with water (Fig. 75). Thus, when this control rod is inserted, the reactivity increases in the bottom part of the core during the initial phase of rod movement.

The control rods are operated by a d.c. motor drive mechanism via a belt cable. The insertion – withdrawal rate in the control mode is 0.2 m/s. In case of an emergency shutdown the control rods are inserted at a maximum rate of 0.4 m/s. The speed is limited by the flow resistance of the water in the control rod channels. Thus, the insertion time of an absorber rod, which has been fully withdrawn from the core, is about 15 s. In addition, a few seconds are required for an absorber rod that has been fully withdrawn from the core to become effective. Therefore, under all operating conditions a minimum number of absorber rods must be partially inserted in the reactor core to provide immediate reduction of neutron flux in an emergency shutdown.

The five levels of emergency shutdown, depending on the nature of the emergency, are complete reactor shutdown, partial reactor shutdown, and preventive controlled power reduction by 20, 50, and 60 %.

In case of *complete emergency shutdown*, all control rods except the short ones are automatically inserted in the reactor core at maximum speed. Examples of situations actuating complete reactor shutdown are

- Power overshoot of 10 % of full power,
- Reduction of the reactor period to 10 s,
- Reduction or increase of the water level in the steam separators,
- Rressure excess in the accident localization compartments, or
- Trip of both turbine generators or of the last operating turbine generator.

In the event of a local power overshoot, withdrawal of the local regulating rod is stopped. In a local emergency power overshoot the two local emergency rods are lowered into the core until the overshoot clears. In addition, automatic reduction of overall power is initiated.

Reactor Process Monitoring System. The reactor process monitoring system provides information on the current status of parameters important for reactor operation and safety. This information includes data from each channel (e.g., flow rate, type of cell charge, rod position), channel failure detection, physical power monitoring system, fuel cladding failure detection, and graphite stack temperature monitoring.

3.3.5. Safety Systems

Like other nuclear power plants, RBMK-type reactors are equipped with extensive safety systems to cope with incidents and accidents. The extent of safety systems installed in a reactor depends on the set of design basis accidents and transients, considered during the design of the plant, that must be handled successfully by the safety systems without damage to the fuel or the environment. Examples of accidents and transients considered during the design of second-generation RBMK-1000 reactors are:

1) Rupture of the largest pipe in the reactor coolant recirculation loops (i.e., the 900-mm-diameter discharge header of the reactor coolant pumps),
2) Rupture of one pressure tube in the graphite stack,
3) Rupture of a reactor outlet pipe,
4) Reactivity transients,
5) Trip of reactor coolant pumps,
6) Turbine trip,

7) Complete loss of normal in-house power supply, and
8) Internal flooding or fire.

Vital safety systems for the RBMK-1000 reactor are the emergency core cooling system, the accident localization system, and the emergency power supply. Safety systems must perform their tasks even if one component fails in the course of an incident or accident. Therefore, safety systems usually consist of three independent trains, each with 50 % of the capacity required for the most demanding incident or accident. The main characteristics of the safety systems of the second generation RBMK-1000 reactors are as follows:

Emergency core cooling system

Number of subsystems	3 (independent)
Capacity	3×50 %
Accumulators	
Number	2 subsystems, 6 tanks each
Capacity	2×50 %
Total volume	25 m^3 per tank
Water volume	13 m^3 per tank
Pressure	10 MPa
Safety injection pumps (damaged half of reactor)	
Number	3 subsystems, 2 parallel pumps each
Capacity	3×500 t/h (3×50 %)
Safety injection pumps (undamaged half of reactor)	
Number	3 subsystems, 1 pump each
Capacity	3×250 t/h (3×50 %)

Accident localization system

Type	pressure supression system for reactor cavity, inlet piping, and main coolant pumps
Design pressure	0.45 and 0.18 MPa, respectively
Number of bubbler ponds	2
Total water volume	3200 m^3
Bubbler pond cooling system	3 pumps (3×50 %)

Emergency power supply

Number of subsystems	3 (independent)
Capacity	3×50 %
Emergency diesel generators	3 (5.5 MW each)

3.3.5.1. Emergency Core Cooling System

The emergency core cooling system is designed to provide cooling to the reactor core and to remove the decay heat in the event of a loss-of-coolant accident. In more recent plants such as Chernobyl units 3 and 4, the emergency core cooling system has been designed to cope with the rupture of the largest pipe in the reactor coolant recirculation loops, i.e., the 900-mm-diameter discharge header of the main coolant pumps. (Former units were designed for the rupture of a 300-mm-diameter subheader.) The emergency core cooling system has three independent trains, each with 50 % of the capacity required (Fig. 76). The three trains of the emergency core cooling system are subdivided into (1) a fast-acting section and (2) a section providing prolonged water supply to the reactor core.

Fast-Acting Section. The fast-acting section supplies water to the damaged half of the reactor core in the first phase of a loss-of-coolant accident (3×50 % of the capacity required), i.e.,

Figure 76. Schematic of emergency core cooling system
a) Reactor; b) Steam separators; c) Reactor coolant pump suction headers; d) Reactor coolant pump; e) Reactor coolant pump discharge header; f) Suppression pool; g) Accumulator; h) Decay power removal cooler; i) Emergency core cooling pump (damaged half of reactor core); j) Condensate storage tank; k) Emergency core cooling pump (undamaged half of reactor core); l) Deaerator; m) Feedwater pump

to the half of the reactor core belonging to the reactor coolant loop that is affected by the loss of coolant. Two trains consist of six accumulators, each filled with water and nitrogen. The nitrogen at a pressure of 10 MPa provides the driving force to inject the water into the damaged half of the core. The total water volume of the accumulators of one train is about 80 m^3. The accumulator systems supply water for at least 100 s during the accident. The third train of the fast-acting section uses the motor operated feedwater pump to inject water from the feedwater system into the damaged half of the core. In case of a loss-of-coolant accident along with a loss of in-house power supply, the feedwater pump is powered by the turbine generators during their rundown for about 45 – 50 s. All three trains of the fast-acting section are connected to the fuel channels of the reactor core via pipes and headers. They are operated by fast-acting valves and automatically switched to the damaged half of the reactor core.

Prolonged Section. The prolonged section of the emergency core cooling system provides cooling to both the damaged and the undamaged halves of the reactor core. Each of the three independent trains consists of two parallel pumps for the damaged half of the core and one pump for the undamaged half. Again, each train provides 50 % of the water required in the most severe design basis loss-of-coolant accident. Immediately after operation of the fast-acting part of the system, the two subsections of the prolonged part are automatically switched to the damaged and undamaged halves of the reactor core, respectively.

3.3.5.2. Accident Localization System

To limit radioactive releases to the environment in a loss-of-coolant accident, parts of the reactor coolant loops of RBMK-type reactors are enclosed by a set of sealed compartments (accident localization system, Fig. 77). The accident localization system consists of:

1) Two compartments, each enclosing the suction and discharge headers of the coolant pumps of one reactor coolant loop;
2) One compartment enclosing the reactor coolant pump discharge subheaders and the piping between the subheaders and the fuel channel inlets;
3) The steam distribution corridor, and
4) The pressure suppression pool (g) at the bottom part of the reactor building with two elevations and a total water volume of 3200 m^3.

Piping not enclosed by sealed compartments includes

1) the core outlet piping between upper biological shield and steam separators;
2) the steam separators;
3) the downcomers from the steam separators to the reactor coolant pump suction headers; and
4) the main steam and feedwater lines.

Figure 77. Schematic of the accident localization system a) Steam separators; b) Reactor coolant pump discharge header; c) Reactor; d) Reactor coolant pump; e) Sealed compartment of accident localization system; f) Concrete structure; g) Suppression pool; h) Check valves; i) Double-stage relief channel; j) Overpressure protection relief pipe

The fuel channels are not enclosed by the accident localization system itself but by the *sealed reactor vessel*, which is not connected to the compartments of the accident localization system.

The compartments of the accident localization system are interconnected by check valves. The two compartments enclosing the suction and discharge headers of the reactor coolant pumps, as well as the distribution corridor, are connected to the two levels of the *suppression pool* by double-stage relief channels. If a loss-of-coolant accident occurs in the part of the reactor coolant loops that is enclosed by the accident localization system, steam released to the sealed compartments is suppressed by the water in the suppression pool via the check valves and the relief channels. Thus, overpressure in the sealed compartments and radioactive releases to the environment are prevented.

In addition, the suppression pool serves as:

1) The water supply for the emergency core cooling system,
2) The heat sink for the overpressure protection of the reactor vessel in the event of a fuel channel rupture inside the graphite stack, and
3) The heat sink for the overpressure protection of the reactor coolant circuit.

Overpressure in the sealed reactor vessel could lift the upper biological shield and lead to massive failure of the fuel channels welded to the upper shield. Therefore, the reactor vessel is connected by large-diameter pipes to special sections of the suppression pool. If a leakage or rupture of a fuel channel occurs, the steam released to the reactor vessel is discharged via these pipes to the water in the suppression pool and overpressurization of the reactor vessel is prevented. For most RBMK-1000 units, the reactor vessel discharge pipes are designed to handle the rupture of one fuel channel. In the most recent units the discharge capacity has been increased to prevent overpressurization of the reactor vessel in the event of rupture of three channels.

The *reactor coolant overpressure protection system* is designed to ensure that the permissible pressure in the reactor coolant system is not exceeded, especially in the case of the unavailability of the main condenser. The system consists of eight main steam safety valves with a total capacity of 5800 t/h, the nominal steam output of the reactor at full power. The main steam safety valves discharge steam from the main steam lines to the water in the suppression pool via piping with a large number of submersible nozzles. In addition to the automatic mode, the main steam safety valves can be opened manually from the control room.

A system with three 50 % trains is used to remove heat discharged into the water of the suppression pool.

3.3.5.3. Emergency Power Supply

In a typical RBMK unit, *normal in-house power* is provided by (1) the two turbine generators (d), (2) the main grid, (3) the auxiliary grid, and (4) a cross connection to the other units at the same

site (Fig. 78). The normal in-house power supply provides electrical power to all of the plant equipment.

Safety-related equipment (i.e., equipment necessary for emergencies) is powered by the *emergency power supply*. The emergency power supply has three independent trains (3×50 %). Emergency power is provided by the normal in-house power supply if the latter is available. In case of a complete loss of normal in-house power, three emergency power diesel generators (6 kV, 5500 kW each) provide electrical power to the three trains of the emergency power supply.

Part of the safety equipment does not tolerate any interruption of power. These systems (e.g., the isolation system of the accident localization system, fast-acting valves in the emergency core cooling lines, the reactor protection system, instrumentation, and control of safety systems) are powered by 0.4-kV busbars supplied by batteries via static converters. Some safety equipment must be provided with electrical energy immediately after the occurrence of specific design basis accidents. Because the diesel generators need time to start and to power the emergency busbars in the event of loss of normal in-house power, this equipment is powered by the turbine generators using their inertial energy during run down.

3.3.5.4. Improvements after the Chernobyl Accident

Following the April 26, 1989 accident at the Chernobyl nuclear power station, RBMK-type reactors have been and will continue to be improved substantially to decrease their sensitivity to the core steam void fraction and increase the effectiveness of safety provisions. Important improvements to decrease the influence of the void coefficient are:

1) Greater enrichment of the fuel;
2) Higher number of fixed absorber rods in the reactor core;
3) Increasing the effectiveness of the existing shutdown system by
   - Increasing the number of control rods that must be partially inserted in the reactor core under all operating conditions,
   - Preventing complete withdrawal of control rods from the reactor core by interlocks (i.e., control rods are inserted at least 1.2 m into the reactor core to avoid a reactivity increase in the bottom part of the reactor core during the first phase of control rod insertion), and
   - Preventing power operation at power levels below 700 MW_e by an automatic trip signal;
4) Installation of an additional fast-acting shutdown system,
5) Increased capacity of the overpressure protection of the sealed reactor vault;
6) Improved information and alarms available to operators to follow the status of important operational and safety-related parameters and to recognize any deviation from authorized domains for operation of the reactor core.

3.3.6. The Chernobyl Accident

The RBMK reactors in the former Soviet Union had a good operating history until 1986. More than 100 years of operation of this reactor type had demonstrated a high degree of reliability. On April 26, 1986, Chernobyl 4 suffered the most serious accident in the peaceful use of nuclear energy. The disaster was caused by violation of procedures, combined with specific characteristics of the RBMK reactor at low power.

The Chernobyl nuclear power station is located about 120 km northwest of Kiev on the Pripyat River. By April 1986, four RBMK units were in commercial operation at the site. Two additional units were under construction. On April 25, 1986, unit 4 of the Chernobyl nuclear power station was to be shut down for routine maintenance. Just before shutdown a special test was scheduled to demonstrate improvements in the capacity of the turbine generators that support essential systems during the first phase of a complete loss of the normal in-house power supply. Key steps in the test procedure were (1) power reduction to 700 – 1000 MW_{th}, (2) tripping the last operating turbine, and (3) measuring the electrical power provided by the turbine generator during its inertial rundown, using four of the eight main coolant pumps as electrical load. At 1: 30 a.m. operators began to reduce the power of unit 4. At noon a power level of

50 % (1600 MW_{th}) was reached, and one of the two turbine generators was disconnected from the grid. At the command of the Kiev load dispatcher, further power reduction was delayed until 11: 00 p.m., which lead to a substantial buildup of the neutron poison xenon-135 in the reactor core. At 11: 00 p.m. the operators continued to decrease reactor power to the test target level of 700 – 1000 MW_{th}. Because of an operator error during switchover of the reactor power control system, reactor power dropped to $< 30\,MW_{th}$ and could not be restored to the level required by the test procedure. Nevertheless the operators decided to keep the plant running to perform the test.

In violation of instructions in the procedures, the power was raised to 200 MW_{th}, far below the level required for stable operation of the reactor. After switching on the two standby main coolant pumps as required by the test procedure, the operators blocked several trip signals to prevent automatic shutdown of the reactor before or during the test–again a violation of operating procedures.

Immediately before the start of the test the status of the reactor was characterized by:

- Low reactor power and high coolant flow rate, resulting in low coolant void fraction and high coolant inlet temperature;
- Blocking of essential trip signals; and
- Complete withdrawal of all control rods from the reactor core (except for the 12 control rods for automatic power control).

In summary, the potential for void formation and power increase was large and safety provisions were substantialy reduced; the reactor thus was highly prone to a power excursion.

When the test began at 1: 23.04 a. m. on April 26, 1986, the last operating turbine generator was shut down as required by the test procedure. The reactor continued operation because of the bypassed trip signals. The four main coolant pumps that were connected to the turbine generator as an electrical load for the test coasted down together with the turbine generator, thus lowering the core coolant flow. Because of the reduction in the core flow rate, the core void fraction and the reactor power began to increase.

After the test had been in progress for about 36 s, the shift supervisor ordered a manual scram because the electrical equipment to be tested was operating successfully. At that time a slight power increase was observed, which was actually the starting point of a fast power ramp. Since almost all of the control rods had been withdrawn completely from the core, several seconds were required for the control rods to move into the core and become effective. This time was too long to prevent a large power excursion. The power excursion destroyed the reactor, and large amounts of reactor core and moderator material were ejected from the reactor building. The hot material ejected from the reactor core started more than 30 fires that threatened the three other units of the power station. Fire brigades succeeded in extinguishing these fires after about four hours.

To decrease the release of radioactive fission products from the damaged reactor core to the environment and to extinguish the burning graphite moderator, the reactor core was covered with a variety of materials (total mass ca. 5000 t) by helicopters. This work was finished on May 6, 1986. By October 1986, a tight concrete structure had been built around the damaged reactor to prevent further release of radioactive fission products from the reactor to the environment.

Figure 78. Schematic of in-house and emergency power supply
a) Main transformer; b) Auxiliary transformer; c) In-house service transformer; d) Turbine generator; e) In-house service power busbar; f) Emergency diesel generator; g) Emergency power supply busbar

During and after the accident, a total of ca. 3 % of the radioactive inventory of the reactor core was released to the environment; more than half of this was deposited in the area surrounding Chernobyl and in other parts of the former Soviet Union. Because of the widespread radi-

ological consequences of the accident, an area up to 30 km from the power station had to be evacuated, part of which will not be habitable for many years. The economic consequences of the accident for the former Soviet Union have been very high. In the meantime, the former Soviet government has decided to shut down units 1 to 3 of the Chernobyl nuclear power station, which are still being operated.

3.4. Heavy-Water Reactors

All nuclear fission reactors that use heavy water (D_2O) to moderate the fast neutrons released by nuclear fission are called heavy-water reactors (HWR). Because heavy-water reactors can be operated with natural uranium as fuel, they are of interest to countries that have economically recoverable natural uranium reserves, despite the high price of heavy water in 1996 ($ 280/kg).

3.4.1. History and Development

The suitability of heavy water as a moderator for natural uranium-fueled reactors was indicated by Werner Heisenberg in 1939, shortly after the discovery of nuclear fission [113]. Although experiments with heavy water and natural uranium were conducted in Germany during World War II, the world's first experimental heavy-water reactor (the so-called CP-3) was built in 1944 in the United States. In the ensuing period a number of *experimental* and *plutonium-producing reactors* were built that used heavy water as moderator. The development of heavy-water reactors for *power generation* began in Canada in 1950, in Germany in 1956, and in other countries in the years that followed. Several designs were developed in the beginning whereas most of these prototype reactors are already shut down or decommissioned.

Prototype or Test Reactors. *Pressure Tube Reactors Using Water as Coolant and Heavy Water as Moderator.* Examples: EL-4 in France, Lucens in Switzerland, Niederaichbach in Germany.
Pressure Vessel Reactors Using Carbon Dioxide as Coolant and Heavy Water as Moderator. Example: A 1-Jaslovské Bohunice in Slovakia.
Boiling-Water Reactors Using Carbon Dioxide as Coolant and Heavy Water as Moderator. Examples: Winfrith in the United Kingdom, Gentilly-1 in Canada, CIRENE in Italy, Fugen in Japan.
Pressure Tube Reactors Using Organic Compounds (Santowax, Therphenyl) as Coolants and Heavy Water as Moderator. Example: WR-1 in Canada.

Power Reactors. *Pressure Tube Reactors Using Heavy Water as Coolant and Moderator.* Examples: CANDU reactors in Canada, India, Pakistan, Korea, and Argentina. These reactors are being further developed as advanced PHWR.
Pressure Vessel Reactors Using Heavy Water as Coolant and Moderator. Examples: MZFR (multipurpose research reactor) in Germany, Atucha 1 and 2 in Argentina.

Nowadays, only pressure tube and pressure vessel reactors using heavy water as moderator and coolant are in commercial operation.

Because of the relatively high investment costs, only a few heavy-water reactors have been able to compete with light-water reactors on the world market (see Table 39). Some of the factors dictating the high specific investment costs are (1) the size of the reactor pressure vessel, or calandria vessel, (2) the necessary segregation of moderator and coolant, and (3) heavy-water conditioning, purification, and upgrading.

In contrast to light-water reactors, *refueling* in heavy-water reactors is performed as a rule on-line (i.e., the reactors can be operated at full power for extended periods). Because the differences in neutron physical properties between cold and hot operating conditions are small, the load can be changed rapidly as and when required. Furthermore, no special control features are required because heavy-water reactors are operated only with low excess reactivity.

Future Trends. The trends in future HWR design and technology include (1) *alternative fuel options* and (2) *improvement of plant design* [114].

Despite its good neutron economy the HWR operated with natural uranium achieves low burnup. Therefore, MOX fuel or slightly enriched uranium is used, which offers a higher burnup at nearly the same fabrication costs. There are plans to use the spent fuel of LWRs in HWRs in a tandem mode.

Table 39. Nuclear power plants with heavy-water reactors

	In operation		Under construction, on order, or planned		Summary

China			2	1 480	2	1 480
Total	34	18 156	12	6 230	46	24 386

Darlington Nuclear Power Station in Canada has the largest HWR units ($4 \times 935\ MW_e$ gross) in operation, unit No. 2 started commercial operation in 1992. Further development of CANDU reactors covers ratings up to $1300\ MW_e$, including features for life extension, rapid load-following capabilities, and shorter construction periods [114]. The CANDU 3 ($450\ MW_e$ gross) has been developed as an alternative to coal-fired stations for small electrical grids. The latest design, the CANDU-80 with a power output of ca. $100\ MW_e$, is suited to a variety of electricity and cogeneration applications. In India, units with $500\text{-}MW_e$ gross output are being designed.

In Germany the Siemens pressurized vessel heavy-water reactors (PHWRs) originate from the multipurpose research reactor (MZFR), which operated successfully for about 18 years. This HWR line was continued in Argentina with the Atucha 1 and Atucha 2 reactors. Improvements in specific areas include reduction of the tritium content in the coolant, control rod drives, spent fuel storage capacity, and alternative fuel cycles. A $380\text{-}MW_e$ advanced HWR of this line (ARGOS) has been drafted in Argentina.

In Japan the advanced thermal reactor (ATR) was originally developed for the utilization of plutonium, recovered uranium, and depleted uranium. A prototype reactor Fugen ($165\ MW_e$), a heavy-water-moderated boiling-water reactor, has been in operation since 1979. An ATR demonstration plant (Ohma Power Station) was scheduled to go into commercial operation in Japan in March 1999. [115].

3.4.2. Design Features

Arrangement of Fuel Rods in the Reactor. Heavy-water moderated reactors require a $D_2O - UO_2$ volume ratio of 16 – 18. To maintain this ratio, bundles of 19 – 37 relatively tightly packed fuel rods are arranged with ca. 25-cm spacing between the bundles. This produces two clearly defined zones:

1) The fuel bundles themselves are accommodated in coolant channels and are swept by *coolant* to remove heat generated by nuclear fission.
2) The zone outside the coolant channels accommodates the *moderator*.

(In light-water reactors the fuel elements are arranged as a heterogenic core. Light water is used as moderator and coolant which are not separated from each other.)

Design. Heavy-water reactors are either of the pressure vessel or pressure tube type. In a *pressure vessel reactor* the coolant channels and the moderator zone are accommodated in a common pressure vessel. Coolant and moderator are kept at the same pressure–but the moderator at lower temperatures–through pressure equalization openings. The coolant channels are therefore not pressure retaining and can have appropriately thin walls.

In a *pressure tube reactor* the moderator zone and the coolant are clearly separated physically. In the moderator zone, pressure and temperature are lower than in the coolant. The pressure tubes are exposed to the full primary system

pressure of ca. 100 MPa. The coolant channels and pressure tubes that serve as coolant-carrying and pressure-retaining parts, respectively, cover the entire length of the moderator zone. To keep heat losses from coolant to moderator low, the coolant channels and pressure tubes are also provided with thermal insulation. Some characteristic design data for heavy-water reactors are given in Table 40.

Coolant. Segregation of the coolant and moderator zones provides different coolant (gases, liquids) options, particularly with pressure tube reactors. In the past, numerous types of coolant have been used, which account for the large variety of heavy-water reactors built worldwide. The ensuing diversification of developments is, however, one of the reasons why heavy-water reactors have not been as successful as light-water reactors.

For heavy-water reactors fueled with natural uranium, only coolants with low neutron absorption coefficients (D_2O, CO_2, He) are suitable. In addition, coolants must be chemically compatible with the reactor materials and must be stable under irradiation and temperature loads, which further restricts the suitability of coolants. Switching to enriched uranium as fuel extends the spectrum of possible coolants, particularly compounds with a high hydrogen content such as light water or organic liquids.

Materials. To decrease the damage from neutron absorption, materials with the lowest possible neutron absorption coefficients must be used, especially in a natural uranium reactor. Zirconium alloys have become the most accepted standard material in the *reactor core*. The most important of these alloys are:

1) Zr – Sn alloys with small additions of Fe, Cr, and Ni (e.g., the standard alloys Zircaloy-2 and Zircaloy-4);
2) Binary Zr – Nb alloys (e.g., Zr – 2.5 % Nb); and
3) Other zirconium alloys (e.g., MgZr; ZrNb 3 Sn 1; ZrCrFe; ZrCuFe).

The alloy silver – indium – cadmium or hafnium is used as material for the *absorber rods*.

As in LWR nuclear power plants, high temperature-resistant fine-grained steels (e.g., 20 MnMoNi 55) are used for the structural parts and pressure-retaining components of the *coolant loops*; inner surfaces in contact with coolant or moderator are generally clad with austenitic steel to keep corrosion rates low.

3.4.3. Types of Heavy-Water Reactors

3.4.3.1. Heavy-Water-Cooled Pressure Tube Reactor

The Canadian heavy-water-cooled pressure tube reactor (CANDU), jointly developed in Canada by Atomic Energy of Canada Limited (AECL) and the nuclear industry, is today the leading heavy-water reactor. About 85 % of the 18 156 MW_e of all heavy-water reactors in operation, under construction, or planned are Canadian CANDU reactors (Table 41). Reactors with

ratings up to 935 MW_e are under construction or in operation [116–120]. Most of the reactors built to date have ratings between 550 and 950 MW_e.

Figure 79. Reactor building of a pressure tube heavy-water reactor (CANDU)

Concept. The reactor is a large, horizontally oriented cylindrical tank, called a calandria, which contains the heavy-water moderator at low pressure and temperature. This tank is penetrated by a number of horizontal fuel channels that contain the fuel assemblies and are swept by the pressurized, high-temperature, heavy-water coolant. Steam generators and coolant pumps are located at each end of the reactor so that flow is in one direction through one-half of the fuel channels and in the opposite direction through the other half.

All primary and moderator system components are located in the containment, which basically forms an envelope around these nuclear components (Fig. 79). The containment system comprises a prestressed, posttensioned concrete structure with a plastic liner and energy sinks that consist of an automatically initiated dousing system and building air coolers.

The Reactor. The reactor (Fig. 80) consists of a cylindrical stainless steel *calandria structure* containing the heavy-water moderator, the reactivity control mechanisms, and 380 *fuel channel assemblies* (600 MW). Each of the fuel channel assemblies consists of a pressure tube (material Zr – 2.5 % Nb) and channel closures at both ends. The fuel channels contain the fuel and heavy-water coolant and pass through the calandria tubes. The gap between each fuel channel and calandria tube is filled with gas to provide thermal insulation. A cooling system dissipates the heat transferred to the moderator from the high-temperature fuel channels, as well as the heat generated in the heavy water itself through interaction with fission neutrons and γ radiation.

Figure 80. CANDU reactor assembly

The calandria is supported by end shields that provide shielding between the reactor core and the fueling machine operating areas. The calandria and end shields are housed in the *concrete vault*, which is steel-lined and filled with light water that serves as a cooling medium and as biological shielding.

The reactor is fueled with natural uranium in the form of uranium dioxide pellets. Approximately 29 pellets, stacked end to end, are sealed in a zirconium alloy sheath to form a fuel element; 37 of these elements are assembled into a fuel bundle (length 495 mm). Each fuel channel accommodates 12 fuel bundles.

Neutron-absorbing systems, both liquid and solid, assist in controlling reactivity. Fast reactor shutdown is achieved by using shutoff rods or liquid poison injection into the moderator.

Reactor System. The primary coolant system circulates heavy water through the reactor fuel channels to remove the heat produced by fission of the uranium dioxide fuel. The heat is carried to the steam generators where it is transferred to the plant's steam – feedwater cycle. Figure 81 shows a simplified overall flow diagram.

Heat Transport System. The main components of the heat transport system are 380 reactor fuel channels, four vertical steam generators, four pumps, four reactor inlet and four reactor outlet headers, one pressurizer, and all the necessary interconnecting piping and valves. The headers, steam generators, and pumps are located above the reactor. At a pressure of 11 MPa the coolant enters the *coolant channels* at 267 °C and leaves at 310 °C. The total mass flow rate is 27 800 t/h. A common *pressurizer* controls the pressure in the heat transport circuits. The heavy water stored in the pressurizer is heated by electric immersion heaters to provide the proper pressure. The heavy water in the calandria is circulated through the moderator system for cooling, purification, and control of the substances used for reactivity adjustment. The inlet temperature to the calandria is controlled at 43 °C.

Auxiliary Systems. Several auxiliary systems, such as the shutdown cooling system, the purification systems, the liquid poisoning system, and the heavy-water collecting and sampling systems, are provided.

Special Features. Fueling is performed during power plant operation. The fuel bundles are pushed into the reactor channel by a remotely operated fueling machine. Spent fuel bundles are discharged simultaneously into another fueling machine at the opposite end of the reactor and then transferred to a water-filled storage bay in a separate building adjacent to the reactor building. Approximately 16 fuel bundles must be replaced each full-power day.

In operting multi–unit plants (e.g., Darlington) 4 CANDU 900 MW_e reactors are arranged in line. A large fueling duct is located under each reactor and runs the entire length of the station. This duct is used as a passage for two mobile fueling machines, which are mounted on trolleys and serve all four units. In addition, the duct serves as a pressure relief connection between each reactor building and a vacuum building. This is a 75-m-high cylindrical concrete structure that is maintained at subatmospheric pressure. It is isolated from the fueling duct and reactor vaults by large self-actuated pressure relief valves.

The reactor design is somewhat different in terms of station power and building – equipment arrangement. The power output was increased to 935 MW_e, and the calandria contains 480 fuel channels, each with 13 fuel bundles.

Design development of CANDU 9 is aimed at a single-unit adaptation of the 900-MW class.

3.4.3.2. Heavy-Water-Cooled Pressure Vessel Reactor

The heavy-water-cooled pressure vessel reactor was developed in Germany by Siemens [121–123]. It was the basis for the 50-MW_e multipurpose research reactor built at the Karlsruhe nuclear research center between 1961 and 1965. This reactor operated very successfully until 1984 when it was shut down for economic reasons (too low rating).

Between 1968 and 1974 the 367-MW_e nuclear power plant Atucha 1 was built in Argentina. The 745-MW_e Atucha 2, another nuclear plant in Argentina, has been under construction since 1980. The following description is based on the latter plant.

Figure 81. CANDU – simplified flow diagram
a) Pressurizer; b) Fueling machine; c) Moderator heat exchanger; d) Moderator pump; e) Fuel; f) Reactor; g) Calandria; h) Headers; i) Four primary pumps; j) Four steam generators; k) Safety valves; l) High-pressure turbine; m) 2×2 High-pressure heaters; n) Deaerator and storage tank; o) Two moisture separator reheaters; p) Low-pressure turbine; q) Generator; r) Cooling water from rivers; s) 2×3 Low-pressure heaters

Concept. The pressure vessel reactor has many common design features with the pressurized light-water reactor. These features include (1) the reactor pressure vessel; (2) the components of the reactor coolant loops; (3) the pressurizer system; (4) the spherical steel containment; (5) the secondary concrete shielding that forms the annulus building; (6) the safety systems; and (7) the instrumentation and control. The layout of the reactor building with leaktight containment, the concrete shield building including the valve compartment for external impact protection, and the annulus in between to accommodate safety-related systems and components are shown in Figure 82.

The Reactor. The *reactor pressure vessel* that forms the pressure boundary of the reactor core consists of the vessel body and the closure head. These two parts are connected by a flange and are made leaktight by a welded lip seal. The closure head accommodates the nozzles for the fuel assemblies, the control rod drive mechanisms, and core instrumentation (Fig. 83).

The *moderator tank* accommodates all core components and separates the moderator area from the coolant flow. The pressures of coolant and moderator are equalized through pressure equalization openings in the moderator tank head, so that no significant pressure differences act on the RPV internals.

The 451 vertical *coolant channels* (material Zry- 4) arranged in a trigonal lattice (lattice pitch 272 mm) pass through the moderator tank. Each coolant channel contains one 37-fuel-rod bundle with an active length of 5300 mm. Coolant enters the inlet nozzles of the pressure vessel, flows downward in the annulus between RPV wall and

moderator tank, and enters the coolant channels from below. It leaves the coolant channels above the moderator tank cover and is routed to the vessel outlet nozzles.

The 18 *control rods* are arranged around the periphery of the cover. To provide adequate space for the on-load refueling machine, control rods are inserted into the reactor core at an angle of about 20°. Filler pieces in the closure head area and in the RPV bottom section are used to displace and save heavy water.

Reactor System. The reactor is operated with natural uranium (UO_2) as fuel and heavy water (D_2O) as the primary coolant and moderator. Figure 84 shows the reactor coolant system

Figure 84. Coolant and moderator system, safety-related system (Siemens/PHWR)

RHR = residual heat removal; LAB = feedwater system

with two parallel reactor coolant loops and four moderator loops.

Coolant Loops. Heat generated in the reactor is passed to the plant's steam and feedwater cycle via the steam generators and moderator coolers. The two reactor coolant loops each contain a steam generator, a reactor coolant pump, a common pressurizer, and interconnecting piping. Heavy water at a pressure of 11.5 MPa is heated from 278 to 312 °C as it flows through the coolant channels. The total flow rate is 37 100 t/h.

To maintain the desired pressure in the primary system and to equalize pressure and volume fluctuations due to changes in temperature, a pressurizer is connected to the reactor coolant loops. It is provided with electrical heating and a spraying system.

Moderator System. The moderator system consists of four identical loops, each with a moderator cooler, a moderator pump, and associated connecting pipings. Heat extracted from the heavy water in the moderator coolers is used to heat the feedwater of the secondary-side steam plant to increase plant efficiency. By changing the feedwater flow, the moderator temperature can be varied between 170 and 220 °C and can thus be used as an additional means of controlling reactivity.

The moderator system must perform several functions. During *normal operation* (left-hand part of Fig. 84) it keeps the moderator temperature lower than that of the coolant. In the *residual heat removal (RHR) mode* the system is reconfigured by changing over certain valves so that residual heat is removed via four independent RHR chains (right-hand part of Fig. 84). In the *emergency cooling mode* the system serves as a high-pressure injection system.

Since altering the moderator temperature greatly affects reactor reactivity, this is used to compensate slow-speed reactivity changes (e.g., xenon poisoning during load-following operation).

Auxiliary and Supporting Systems. Different auxiliary and supporting systems back up reactor system operation. These include a cleaning system for removing corrosion products; a gas-handling system for collecting, treating, and storing gases (deuterium, fission gases) produced in the different parts of the reactor system; and a conditioning and upgrading system for contaminated and downgraded heavy water.

Special Features. To achieve a high burnup, the heavy-water-moderated reactor – with little excess reactivity of the uranium dioxide fuel – requires fuel shuffling and replacement during power plant operation. Refueling is performed automatically by one refueling machine and is monitored from the control room. Normally, approx. two fuel assemblies are replaced in the reactor each full-power day.

This type of reactor is designed for uranium dioxide fuel. However, several different fuel cycles are possible without major plant modifications. These alternatives increase fuel burnup and uranium exploitation, and ultimately result in lower fuel cycle costs.

3.4.3.3. Pressure Tube Boiling-Water Reactor (Decommissioned)

Because expensive heavy water should not be used in the large-volume cooling system of a boiling-water reactor for economic reasons, heavy-water-moderated boiling water reactors [type Winfrith SGHWR (steam-generating heavy-water reactor), Fig. 85] are of hybrid design: light water as the heat-transfer medium flows in the pressure tubes, whereas the heavy-water moderator is accommodated in a tank (calandria vessel). Because of the inevitable neutron losses with this variant through absorption in the light water and structural materials, the reactor can be operated only with slightly enriched nuclear fuel. The ATR concept developed in Japan for commercial application provides for the use of fuel rods containing plutonium (ca. 2.5 % enrichment with fissile material).

Concept. The reactor consists of a calandria vessel filled with heavy water and maintained at low pressure. Numerous, vertically arranged, thermally insulated coolant channels pass through the calandria vessel. The plant also has two steam drums into which the water – steam mixture from the coolant channels is fed (Fig. 86). Each coolant channel contains one fuel assembly from which heat is removed by boiling water.

The Reactor. In the Japanese ATR reactor, 616 coolant channels pass vertically through the calandria vessel. The coolant channels are formed by the calandria tubes, which are firmly connected to the calandria vessel, and by the pressure tubes arranged concentrically inside the calandria tubes. The material used for the pressure tubes is steel (material A 308) outside the reactor core and Zr – 2.5 % Nb in the reactor core. The gap between pressure tube and calandria tube is filled with carbon dioxide for insulation and heat removal.

Each pressure tube contains one fuel assembly, and coolant (H_2O) flows upward through the pressure tubes from below. The fuel assemblies are 36-rod bundles (rod diameter 14.5 mm, length ca. 3700 mm). A Zr – 2.5 % Nb alloy is used as cladding material. Characteristic design data from the Fugen reactor [124] operating in Japan since 1979 and the planned prototype reactor ATR [114] are compiled in Table 40.

Reactor System. Two recirculation pumps transfer the *coolant* at a pressure of ca. 6.7 MPa from the steam drums into two distribution systems from which it is routed into the individual coolant channels. Light water enters the reactor from below at 277 °C and is partially evaporated as it passes through the coolant channels. The steam – water mixture is routed to the steam drums at 284.5 °C. The saturated steam (ca. 6.8 MPa) flows from the steam drums via main steam lines to the turbine and is subsequently condensed in the turbine condenser. Feedwater is pumped back into the steam drums and mixed with the reactor cooling water (Fig. 86).

The *moderator circuit* is separated from the steam – water cycle. Moderator temperature is maintained at ca. 80 °C, i.e., the calandria vessel is at normal pressure. The pressure tubes can be handled individually during operation. The fuel assemblies are inserted and replaced from below by using a remotely controlled fueling machine. Control rods containing boron carbide are in-

Table 42. Breeding ratio of European fast breeder reactors

Reactor	Country	Status	Breeding ratio
PFR	United Kingdom	decommissioned	1.0
Phénix	France	operational	1.16

Superphénix	France	scheduled for decommission	1.24
EFR	France, United Kingdom, Germany	design	1.0 – 1.15

serted into the calandria vessel from above for control purposes.

Special Features. Whereas in the Fugen reactor the level of the heavy-water moderator is normally used for control, the planned ATR is equipped with 13 steel control rods and 76 control rods containing boron carbide, which are inserted into the reactor from above. In addition, a boric acid injection system is also provided. As in light-water reactors, the moderator is poisoned with neutron-absorbing boric acid for long-term control.

4. Fast Reactors

4.1. Function and Design

4.1.1. General Aspects

Fast reactors are employed for electricity generation like light-water reactors, but they may also be used to balance fuel inventories of reactors. In case of high energy demand the economic importance of fast reactors, used as breeder reactors, is based on their ability to produce more new fuel from otherwise nonutilizable waste uranium than they simultaneously consume [125], [126]. This is made possible by the fact that fast breeder reactors, unlike light-water reactors, do not operate with moderated neutrons, but directly with the energy-rich fast neutrons arising from nuclear fission. By the action of fast neutrons, nonfissile ^{238}U (which is contained in natural uranium to the extent of 99.3 %) is converted to fissile plutonium ^{239}Pu:

$$^{238}_{92}\mathrm{U} + ^{1}_{0}\mathrm{n} \longrightarrow ^{239}_{92}\mathrm{U}$$

$$^{239}_{92}\mathrm{U} \longrightarrow ^{239}_{93}\mathrm{Np} + \mathrm{e}$$

$$^{239}_{93}\mathrm{Np} \longrightarrow ^{239}_{94}\mathrm{Pu} + \mathrm{e}$$

The breeding ratio (see Section 1.3.8) is a measure of the excess plutonium produced in the reactor. It is defined as the ratio of production to consumption of fissile isotopes. A reactor is called a breeder if its breeding ratio is > 1; otherwise, it is referred to as a converter.

Light-water reactors are unable to utilize more than 1 % of the uranium fuel for energy production. Therefore, worldwide reserves of uranium (with economically justifiable costs of extraction) could cover present electricity consumption for only a few decades if used exclusively in light-water reactors. On the other hand, fast breeder reactors can utilize uranium 60 times more efficiently; i.e., they can produce

Figure 86. ATR – simplified flow diagram
a) Calandria tank; b) Heavy water; c) Fuel assembly; d) Steam drum; e) Control rods; f) Pressure tube; g) Water pumps; h) Turbine; i) Generator; j) Condenser

60 times more energy from a given amount of uranium than light-water reactors can. The dependence of uranium utilization on the conversion or breeding ratio is shown in Figure 87. At a breeding ratio of 1.0, uranium utilization increases dramatically and reaches its limit at about 60 % [127]. The breeding ratios of some European fast breeder reactors are listed in Table 42.

Figure 87. Uranium utilization as a function of conversion or breeding ratio
(High-converters are new types of PWR with highly enriched fuel that are in the developmental stage.)

The total amount of energy that could be produced from the known reserves of uranium worldwide by using fast breeder reactors is substantially higher than the sum of all fossil energy reserves [128] (see Fig. 88). Fast breeder reactors can be employed commercially only if their development continues. In this way, a marked decrease in the specific uranium requirement could be achieved, as well as an efficient utilization of the plutonium obtained in reprocessing spent fuel elements from light-water and high-temperature reactors [130].

Figure 88. Economical availability of worldwide energy resources (in 1986). By comparison, water power potential $< 1.5 \times 10^6$ t SKE/a. (SKE = German Steinkohleneinheit), 1t SKE=29.3GJ. $*$ Cost of extraction ≤ 80 \$/kg uranium.

The possibility of artificially producing fissile material and being independent of natural re-

sources was one of the early considerations in the use of energy from nuclear fission. In 1951 the EBR-1 (experimental breeder reactor) in Idaho, United States, succeeded for the first time in generating electricity from nuclear energy with a fast liquid-metal (Na – K) reactor [129].

During operation, fast breeder reactors require supplies of only nonfissile waste uranium and produce an excess of plutonium over and above their own requirements. This plutonium can then be used in other fast breeder reactors. Thus, the cost of electricity generated by fast breeder reactors is largely independent of the price of uranium, and safe supply to the power industry is substantially improved [131].

The annual consumption of natural uranium will decrease worldwide if fast breeder reactors are increasingly employed (see Fig. 89). This reasoning is based on the assumption that the rate of increase in nuclear power installations will follow the curve in Figure 90 worldwide and that fast breeder reactors with uranium – plutonium oxide fuel and a breeding ratio of 1.15 – 1.20 will be employed by 2010 [132], [133].

Figure 89. Annual consumption of natural uranium (worldwide) in fast breeder reactors

Figure 90. Nuclear power output (worldwide)

Nevertheless, the energy need in the last two decades was less than predicted at the time when the decision was made to built the first industrial size fast breeder reactors such as BN 600 and Superphénix. Therefore, the new fast reactor programs were slowed down or even abandoned. A survey of fast breeder reactors is given in Table 43 [138–147]. On the other hand the problems of the back-end of the nuclear fuel cycle, especially the waste disposal, become more important. In this framework fast reactors gain interest because of their capability to produce various fast neutron spectra. This particularity may be used to transform fission and conversion products from light-water reactors, which need particular precautions for waste disposal, into other products which are easier to handle. These products are mainly plutonium which may be used to produce atomic weapons and minor actinides that are of concern for due to their long half-life. In this framework the role of plutonium may be modified depending on national policies. There may be nations who do no longer use plutonium as a fuel but consider it as waste that is to be treated. Others continue to see plutonium as a potential energy source. At present various methods to adept fast reactors to the new scope of plutonium conversion and actinide transmutation are under investigation: One possibility is to modify the core of fast breeder reactors by introducing plutonium and minor actinides in specific, highly enriched core fuel (CAPRA

core = "Consommation Accrue de Plutonium dans les Réacteurs Rapides"; English: Increased Plutonium Consumption in Fast Reactors). Another one is to combine a subcritical fast reactor with a spallation source in order to produce hard neutron spectra for efficient actinide transmutation. This idea is now under evaluation in various R & D organizations under the keywords Hybrid Reactors and Accelerator Driven Systems. At present the nuclear industry is beginning to evaluate the industrial relevance of this kind of reactor.

Coolant. *Water* cannot be used for heat transfer because it would moderate the neutrons produced by nuclear fission, as in light-water reactors. Former research and developmental work on *steam cooling* has been discontinued in particular because of the too low breeding ratio. Similarly, cooling with *helium* is no longer being pursued because the high power density in the core requires especially extensive measures for heat removal. The fast breeder reactor operating with liquid *sodium* is the only technically safe concept that can guarantee a low-risk and ecologically beneficial supply of electric power for centuries. Sodium-cooled fast breeder reactors are technically feasible and can be operated reliably with the sodium technology fully under control [134], [135]. In fact, the French Superphénix achieved its full output of 1200 MW_e at the end of 1986 [136].

Status and Future Developments. The present state of fast reactor development in Europe is demonstrated by the EFR (European Fast Reactor) project. In planning since 1988 [137], this project combines different national fast reactor variants in a common concept. The present EFR reference design is the most advanced economic optimization of a fast reactor taking into account current safety requirements, operating experiences gained in the past, and approved updated technological knowledge. Nevertheless, abundance of energy supply that will reduce near-future interest in EFR fast reactor development, leads to a re-evaluation of related R & D long term objectives towards fuel cycle back-end and waste management within fast reactor systems.

4.1.2. Sodium as Coolant for Fast Reactor Power Plants

The low neutron moderation, which enables a high breeding ratio, and the excellent heat-transfer properties of sodium make it a particularly suitable coolant for a fast core. However, a specially designed plant is required if sodium is to be used [148–150].

Thermal Properties. A comparison of the thermodynamic properties of sodium and water (Table 44) shows that sodium has a higher melting point and boiling point than water, excellent heat transport properties, and a relatively low specific heat capacity.

Table 44. Comparison of the thermodynamic properties of sodium and water

	Sodium	Water
Density, kg/m^3	850	1000
mp (0.1 MPa), °C	98	0
bp (0.1 MPa), °C	883	100
Specific heat capacity, $kJ\,kg^{-1}\,K^{-1}$	1.3 *	4.2 **
Thermal conductivity, $kJ\,m^{-1}\,h^{-1}\,K^{-1}$	260 *	2.1 **
Viscosity, Pa · s	3×10^{-4} *	10×10^{-4} **

* At 400 °C.
** At 200 °C.

The concept of the plant leads to the following:

1) The plant can be designed as a low-pressure system even at high temperature. The steam conditions of conventional power plants can be achieved, with the resulting high efficiencies.
2) The sodium level in vessels has to be protected against contact with the atmosphere by an inert cover gas, usually argon or nitrogen. Due to the fact that sodium plant loops operate far below boiling temperature of the coolant, the overpressure of the cover gas is low. Thus the operation pressure in the loop depends mainly on the dynamic pressure in the coolant flow and the geodetic pressure. In real plants the overpressure in operation at the lowest point does not exceed 15 bar. For this reason, large cross-sections of piping are not in danger of opening up due to sudden breakage, and large leaks are unlikely to occur in vessels. In case of a structural failure of the sodium containing structure (leak, crack) no violent pressure build-up in the reactor containment occurs. The pressure transient in the containment atmosphere depends only on thermal effects of the release of the hot coolant (and not on evaporation effects as in water-cooled reactors). Therefore, the design pressures of the containment system are low with correspondingly greater freedom of design. In case of malfunction, excess heat can be absorbed by the heat capacity of the remaining coolant without significant pressure increase because of the large difference between the operating temperature of ca. 550 °C and the boiling point of sodium (ca. 1000 °C) at the reactor pressure. Therefore, the effects can be safely controlled.
3) Although the power density in the core of a fast reactor is high, the good heat exchange properties of sodium allow heat removal throughout the range of permissible temperature gradients between the fuel rod bundle and the sodium. For the same reason, the specific heating surface requirement in heat exchangers is low.
4) The low specific heat capacity of sodium in comparison to water necessitates large coolant temperature ranges (i.e., temperature difference core outlet – core inlet) with approximately the same rate of coolant circulation as in pressurized-water reactors.
5) The great temperature range between ambient temperature and operating temperatures of about 550 °C requires extensive measures for compensation of thermal expansion. Components are designed to withstand high temperatures.
6) The good heat-exchange properties of the coolant, high operating temperatures, and large coolant temperature ranges require extensive temperature stress analyses and components that are designed to be as insensitive to thermal shock as possible.
7) For start-up and maintenance of readiness for operation, the sodium-containing components and pipes must be heated either electrically with a heating cable or with heating gas.

Nuclear Physical Properties. The nuclear physical properties of sodium may be summarized as follows:

1) Sodium has a low moderation capacity; therefore, the fast neutron spectrum required for fast reactors can be obtained. For the same reason fast reactor cores can be designed for multiple purposes as, e.g., burning of plutonium (breeding gain < 1) or transformation of minor actinides.
2) Sodium is strongly activated while flowing through the reactor core by the following reactions:

$$^{23}\mathrm{Na}\ (\mathrm{n}, \gamma)\ ^{24}\mathrm{Na}$$

$$^{23}\mathrm{Na}\ (\mathrm{n}, 2\,\mathrm{n})\ ^{22}\mathrm{Na}$$

For this reason, parts of the plant through which the core coolant flows are accommodated in strongly shielded rooms. These rooms are not accessible during operation and can be entered only after the plant has been shut down and 10 – 14 days have passed to allow for the decay of ^{24}Na.

Chemical Properties. Sodium undergoes a strongly exothermic reaction with water; hot sodium reacts with oxygen. To protect the reactor from reactions caused by the rupture of a pipe in the steam generator and to prevent reactions with highly radioactive sodium, the coolant in the reactor circulation system (primary circuit) does not enter the steam generator directly. Rather, they are separated by a nonradioactive intermediate heat-transfer circuit (secondary circuit). The compartments with the primary system are maintained under a nitrogen atmosphere with a low oxygen content. Therefore, in the event of accidents involving sodium leakage, the possible burning of activated sodium is excluded.

The secondary circuit is provided with a pressure relief system to safely remove reaction products and limit a pressure buildup due to the sodium – water reaction:

$$2\,\mathrm{Na}_{(l)} + \mathrm{H_2O}_{(l)} \longrightarrow \mathrm{Na_2O}_{(s)} + \mathrm{H_2}\quad \Delta H^{\circ}_{298} = -\,134.3\,\mathrm{kJ/mol}$$

Both ferritic and austenitic steels can be employed because sodium with a low oxide content is minimally corrosive. The oxide content is always kept low by use of an appropriate purification system. All free sodium surfaces are covered with argon to prevent stronger oxide contamination or inflammation of sodium in the presence of oxygen.

Mechanical Properties. The coefficient of fricton of metallic surfaces that are wetted with sodium is higher than that of pure metal surfaces. For this reason, special pairing of materials is required for surfaces that slide over each other. This is especially important in the handling of core elements.

4.1.3. Plant Concepts for Fast Reactor Power Stations

Two concepts are employed in the design of the primary circuit system of fast breeder reactors (with sodium as coolant):

1) The *pool concept*, in which the pump and intermediate heat exchanger are integrated into the reactor vessel.
2) The *loop concept*, in which the pump and intermediate heat exchanger are located outside the reactor vessel in shielded and nitrogen-inert rooms. They are connected to the reactor vessel by a piping system.

No serious technical, safety, or cost-related differences exist between these two concepts. The pool concept is the concept of choice for the EFR because with the Superphénix (SPX), a plant having a power range $> 1200\,\mathrm{MW_e}$ has already been realized by using this concept.

Figure 91 shows a schematic of the nuclear power plant SNR 300 (Kalkar), which has a loop reactor [151], [152]. The Japanese demonstration fast reactor plant Monju follows the same design principle. The schematic of the French Superphénix, a fast breeder with a pool reactor, is depicted in Figure 92 [153], [154].

All fast reactor power stations have a primary and a secondary sodium circuit. Sodium in the primary circuit flows through the reactor core and transfers absorbed heat energy to the sodium of the secondary circuit in intermediate heat exchangers (IHX). This secondary sodium circuit transports heat energy to the conventional water – steam cycle via steam generators. The steam thus produced passes to the steam turbine,

Figure 91. Schematic of SNR300 (loop concept)
A) Reactor building; B) Steam generator building; C) Powerhouse; D) Power supply system
a) Pump; b) Reactor vessel with internals; c) Intermediate heat exchanger; d) Superheater; e) Evaporator; f) Preheater; g) Turbine; h) Generator; i) Condenser; j) Cooling tower

which powers the generator to generate electricity. In this way, a rigorous separation is obtained between the first (nuclear) and the third (conventional) heat transfer system (= water – steam system). The pressure in the secondary circuit is always higher than in the primary circuit. Thus, in the event of leakage in the intermediate heat exchanger, no radioactive sodium from the primary system can enter the practically nonradioactive sodium of the secondary system.

In the *pool concept*, the reactor vessel is enclosed in a second container, the safety vessel, to ensure that the reactor core is always covered with sodium. Therefore, the core can be cooled, even in case of leakage in the reactor vessel or in the primary circuit. In the *loop concept* the primary circuits are generally arranged above the reactor core level in order to prevent the reactor vessel from draining by siphon effect. Those parts of the primary loops that are arranged below the reactor core level are equipped with a protection against loop draining by a double envelope of the structure. Information on core, fuel, sodium temperature, and main steam conditions is provided in Table 45. The principal steam data of fast reactors are similar to those of a conventional steam power plant. For this reason, fast reactor power plants have a thermodynamic efficiency > 40 %.

4.1.4. Plant Arrangement

A longitudinal section through the reactor, fuel handling building, and turbine hall of the Superphénix is shown in Figure 93 [155].

4.1.5. Components and Systems

The most important characteristics of the different systems and components of sodium-cooled fast reactors are described below (using the SNR 300 as an example of a typical loop reactor and the Superphénix as the most powerful pool reactor).

Reactor Core. A cross-section of the core of SNR 300 is shown in Figure 94 [156], [157]. The core consists of hexagonal elements, which are radially subdivided (starting from the inside) into the following three zones:

Table 45. Data on core, fuel, sodium temperature, and steam conditions of fast breeder reactors

1) The *fission zone* in which almost all the reactor power is produced. This zone is normally subdivided into two enrichment zones (inner and outer zone in Fig. 94).
2) The *blanket*, which contains the blanket subassemblies. Here, ^{238}U is converted to ^{239}Pu. The fission zone is radially and axially surrounded by the blanket.
3) The *reflector zone*. The subassemblies of this zone primarily shield important structures located around the core (core shroud, reactor vessel, plus intermediate heat exchangers and pumps in the pool concept).

Figure 94. Transverse section of SNR300 with Mark Ia core (first and second cycle)

The *fuel* used in today's fast reactor power plants is a mixture of uranium dioxide and plutonium dioxide. To achieve better power distribution, the inner fission zone has a lower enrichment with plutonium than the outer one. Axially movable absorber rods made of boron carbide are used for control and shutdown. These are located primarily in the inner zone (on fuel element positions) and are uniformly distributed over its cross-section.

The entire core structure is fixed by the diagrid (grid plate) and the core shroud. This diagrid is also used to guide the sodium coolant to different core zones. In this process, sodium flows upward through the core.

Reactor Vessel System. The reactor vessel system consists of the reactor vessel, the safety (guard) vessel, vessel internals (shield tank, guiding system for internal flow, and core support structure), and the rotating top shield. The reactor vessel system of the SNR 300 is shown in Figure 95 [158], [159]. The free surface of the sodium contained in the reactor vessel is always blanketed with argon. The vessel room is both the collecting compartment and the expansion vessel for the primary circuits. The reactor vessel is basically not pressure stressed because of the closed entry plenum below the grid plate. All pipes of the primary heat-transfer system are connected to the vessel above the sodium minimum level in the vessel that is required for decay power (residual heat) removal.

tem, which consists of the primary pumps and the intermediate heat exchangers. A section of the Superphénix reactor is shown in Figure 96.

Fuel Handling. The economics of the fast breeder fuel cycle require that the ex-core period of the fuel (time between unloading of spent fuel and blanket subassemblies from the reactor core and refueling with reprocessed fuel) is kept as short as possible. However, because the decay power of the spent fuel considerably hinders the handling and treatment of these assemblies, newer fast reactors are provided with facilities in the reactor vessel outside the core shielding to store spent fuel for an operational cycle (ca. 1 year). Hence the fuel assemblies remain continually under sodium during this period. After this storage time the decay power decreases to < 10 kW per fuel assembly. The fuel assemblies can then remain without sodium cooling during the handling transfer to the spent fuel storage. In Superphénix the spent fuel elements are cleaned by a special cleaning process, which is a chemical reaction of sodium to yield sodium hydroxide or sodium carbonate, and subsequent washing with water [160]. In Superphénix the washed elements are transferred to a water storage. This facility allows to store several core loadings in order to cover the time span before industrial reprocessing.

To facilitate the *refueling process* (Fig. 97), which is carried out after the reactor has been shut down and the temperature of sodium has fallen to ca. 200 °C, the central part of the reactor roof consists of a rotating top shield. With this shield the structures arranged above the core (control mechanisms and instrumentation) are swung to one side, making the fuel and blanket subassemblies accessible to the handling equipment located in the rotating top shield. The spent and decayed subassemblies, along with the new assemblies, are removed from or inserted into the reactor vessel, respectively, by using a shielded handling flask. The spent fuel and blanket subassemblies are subsequently prepared for transport to reprocessing facilities in a hot cell (i.e., discharge cell for irradiated fuel) and are then loaded into a transport cask. A transport cask provided with adequate shielding and fall protection has a mass of approximately 100 t.

Heat-Transfer Systems. Heat generated in the reactor is transferred to the water – steam cycle by the primary and secondary heat-transfer

systems. The most important components are sodium pumps, intermediate heat exchangers, steam generators, and piping (see Figs. 91 and 92). The principal data of the components of the fast breeders SNR 300 and Superphénix are summarized in Table 46 [161–164].

Sodium Pumps. Single-stage, single-flow, speed-controlled centrifugal pumps are provided for the circulation of sodium in primary and secondary circuits. The free sodium surface in the pump casing is covered with argon gas. The vertical shaft has double bearings – an oiled roller bearing at the upper end and a sodium-lubricated hydrostatic radial bearing at the lower end in the region of the impeller. The use of electromagnetic pumps is limited to sodium auxiliary plants (e.g., purification systems) because of their low efficiency.

Intermediate Heat Exchangers. The intermediate heat exchangers are the link between the primary and secondary circuits. Here, heat produced in the reactor is transferred from radioactive primary sodium to nonradioactive secondary sodium. The design of intermediate heat exchangers is shown in Figure 98. These devices can have very compact structures because of the good heat-transfer properties of sodium and because of the use of thin-walled tubes (made possible by the low pressure of sodium). This is a great advantage for the pool reactor because the intermediate heat exchanger is located in the reactor vessel.

Figure 98. Intermediate heat exchanger (design principle)
A) Loop type; B) Pool type

Figure 99. Steam generator
A) Straight tube type; B) Helicoidal tube type

Steam Generators. Extremely stringent quality requirements must be met by the steam generators because the sodium and water flowing through these components are separated only by a tube wall. In the event of a leak, these two media would react chemically with each other. To limit the pressure buildup in the secondary circuit that would then develop, steam generators are provided with fast-responding rupture disks on the sodium side. These allow the reaction products to be removed into a pressure relief system. Different types of steam generators are used, depending on the latest technological developments and the performance required (see Fig. 99).

Auxiliary Systems. Fast reactor power plants that use sodium as coolant require special systems to guarantee safe operation and the functioning of the primary heat-transfer systems. The required purity of sodium is produced, measured, and monitored in *purification systems. Argon* is used in every case when a gas is necessary as operation and control fluid and this fluid is in permanent contact with the sodium coolant. Argon systems are used for the following tasks:

1) As cover gas for all free sodium surfaces in the reactor vessel, sodium pumps, sodium tanks, and some types of steam generators.
2) For buildup and control of the required system pressures at different operating states, and generation of excess or subatmospheric pressure for sodium decanting (operating pressure in reactor vessel ca. 0.12 MPa).
3) To supply handling devices and reactor top shield with sealing, rinsing, and pressurizing gas for seals and compartments.
4) For collecting and treating of radioactive gases and controlled release of treated gas to the environment.
5) For early detection of damages of fuel assemblies in the reactor vessel.
6) For purification of argon from impurities and fission products.

In case of a leak in the steam generator, *pressure relief systems* in the region of the steam generator prevent damage (especially to the intermediate heat exchanger) that results from sodium – water reactions. In addition, these systems limit the spread of reaction products in the secondary circuits.

The decay power removal after reactor shutdown normally occurs via the cooling-water cycle of the steam turbine plant. If this cooling chain fails, a multifunctional *decay power removal system* is available (see Fig. 100). The decay heat is first transferred to immersion coolers ar-

ranged in the reactor vessel and then passed to a sodium – air heat exchanger via sodium circuits [165], [166].

Figure 100. Decay power removal system
a) Intermediate heat exchanger; b) Sodium – air heat exchanger; c) Immersion cooler; d) Hot plenum; e) Core; f) Cold plenum; g) Pump

Other systems characteristic of sodium-cooled fast reactors are *inert gas systems* that maintain the plant rooms of the radioactive sodium systems (mainly in loop reactor systems) under a neutral gas atmosphere in order to prevent sodium fire in case of a leak. In these cases nitrogen is used as inert gas. Another role of the inert gas systems may be cooling and heating of components and systems.

Since sodium has a melting point of 98 °C, all sodium components and piping are provided with *facilities for heating*. Heating is carried out either by an electric trace heater or by hot argon or nitrogen.

Instrumentation and control facilities, as well as power supply, are attached to all systems. Specially developed instruments for measuring pressure, level control, flow, and oxygen content in sodium have been employed for sodium systems.

Steam Turbine Unit. The steam turbine unit is essentially identical to that in conventional units because the steam conditions of a fast reactor power plant are similar to those of conventional power plants. Special facilities include cooling systems for decay power removal.

4.2. Materials [167]

4.2.1. Nuclear Fuels

In principle, the fuels uranium and plutonium can be used in two forms: as pure metals or as ceramic compounds (oxide, carbide, or nitride). Metallic fuel produces a higher rate of burning because of its higher uranium density. However, its disadvantages are a limited operating temperature because of crystallographic transformation, its low melting point, and its radiation properties at high burnup.

Ceramic fuels with an isotropic crystal structure and a production-related porosity for the storage of fission products achieve a high degree of burnup. Today, oxidic nuclear fuel is used almost exclusively. Currently under development are carbidic and nitridic fuels, which give a large breeding ratio in combination with a lower plutonium stock in the reactor core. Oxidic fuel is prepared as pellets by sintering. Great demands are made on the homogeneity of the two components of the mixed oxide (UO_2 and PuO_2) and on their solubility in boiling nitric acid in accordance with the initial stage of the PUREX process.

4.2.2. Cladding and Structural Materials for Fuel Elements

A list of the cladding and structural materials of fast reactors with sodium cooling is presented in Table 47. The stress conditions of the cladding and structural materials are characterized by the sodium-specific corrosion processes that occur at high temperature (up to 700 °C for the cladding material and 560 °C for the structural material). In addition, this material is stressed by the high flux ($> 10^{23}$ n/cm^2) of fast neutrons. The fuel cladding tubes are also subjected to interactions with the fuel. Currently, cold-formed austenitic steels are preferred [e.g., the titanium-stabilized material X10 NiCrMoTiB 15 15 (1.4970) for the SNR 300 and

* IHX = Intermediate heat exchanger.

type 316 modified for the Superphénix]. Short-term and long-term values are markedly increased by approximately 20 % cold forming. Titanium-stabilized steels have improved long-term strength as well. The short-term strength is increased further by irradiation at 400 – 450 °C, whereas above 500 °C the opposite recovery processes come into effect. Reduction of the ductility of the material due to irradiation is, however, especially important in the design. For this reason, the primarily temperature- and stress-dependent creep (resulting from the inner pressure of fission gases in the fuel rod) must be limited to 0.2 %. The time-dependent creep strength under irradiation is of little importance in design of the core element structures because of the low primary stresses. Swelling and irradiation-induced creeping are caused by the extremely fast neutron flux. The phenomenon of swelling is less pronounced in cold-formed steels than in solution-treated materials. The fuel assemblies are designed to control swelling to an extent of 10

4.2.3. Structural Materials for Components

Austenitic and ferritic steels are employed in the components of a fast reactor in both reactor areas and heat-transfer systems (see Table 47). The behavior of both materials in sodium has been successfully proved. Properties that are important for materials selection are strength, corrosion resistance, and the availability of design data. Relevant regulations must be considered.

4.2.4. Application of Materials in Sodium Systems

The *corrosion effects* resulting from the use of materials in sodium are minor and have been determined by extensive experimentation and operating experience. Erosive corrosion is influenced most strongly by the oxygen content of sodium. Other important parameters are the temperature and flow rate of sodium. After an initial phase, the rate of corrosion remains constant during long-term operation under constant operating conditions. No significant differences exist between austenitic and ferritic steels. Allowances are made for corrosion effects by additions to wall thickness that do not interfere with design.

During reactor operation, the sodium systems operate with an oxygen concentration of ≤ 5 ppm by the use of purification systems. In this way, a sufficiently low corrosion rate is achieved (e.g., 4 µm/a at 550 °C with type 316 ss material). Inside the reactor plant, the small reduction in wall thickness caused by erosive corrosion need be considered only in the case of thin-walled components (e.g., cladding tubes of the fuel elements and tubes of the intermediate heat exchangers).

The material removed from the high-temperature zones of the sodium system is deposited at low temperature regions. An example is the transfer of carbon. Since the solubility of carbon in sodium increases with temperature, carbon is dissolved in sodium in zones of higher temperature, transported with the coolant, and deposited in low temperature regions if the equilibrium

concentration is exceeded. This mass transport (*carbon transport*) causes, for example, a reduction in strength of the material in hot zones due to decarburization and deposition of carbides in colder zones.

The *transfer and deposit of radionuclides* are very important for the accessibility of the primary sodium systems to maintenance and repair. These radionuclides are generated by the activation of corrosion products from the cladding and structural materials, as well as activation of the coolant and its impurities; and by fission products from defective fuel rods. Among activated corrosion products, the dominating nuclide is ^{54}Mn ($t_{1/2} = 312$ d), which is deposited predominantly in the cold part of the primary system. Considerably less radioactivity is generated by ^{60}Co ($t_{1/2} = 5.3$ d), which is deposited primarily in the hot area. In addition, both ^{22}Na ($t_{1/2} = 2.6$ d) and ^{65}Zn ($t_{1/2} = 244$ d) contribute markedly to the radioactivity. In case of operation with defective fuel rods, the dominating nuclide is ^{137}Cs ($t_{1/2} = 30.1$ d). Cesium traps are used to remove cesium from sodium.

4.3. Chemical Engineering

4.3.1. Monitoring Sodium Purity

The measurement and control of impurities in sodium are imperative for the operational safety of sodium-cooled fast reactors. Changes in the "normal" concentration of impurities indicate to the plant engineer certain variations or malfunctions in the operation, in time to take the necessary countermeasures. In fact, determination of the impurities in sodium provides information on corrosion, mass transport, damaged fuel rods, and the penetration of air, water, or oil. Above all, the concentrations of oxygen, hydrogen, and carbon must be constantly monitored.

Specific analytical methods are available for determination of each of the impurities in sodium [168–170]. In principle, a distinction must be made between measuring instruments that record continuously during reactor operation and measurements conducted discontinuously, which involve sampling of sodium and subsequent laboratory analysis.

4.3.1.1. Measuring Instruments

Instruments installed in the plant are increasingly used to monitor sodium purity because, unlike chemical analyses, they provide data continuously and are usually very sensitive.

Figure 101. Plugging meter
a) Solid iron; b) Solenoid; c) Sodium outlet; d) Air inlet; e) Thermocouple; f) Orifice; g) Needle; h) Sodium inlet; i) Air outlet

Plugging Meter. Information on the amount of *impurities* that may lead to deposits of reaction products and corrosion effects in the plant, is necessary in order to prevent any disturbance of plant operation. Mainly the amount of oxy-

gen, hydrogen, and carbon is to be monitored. Information is obtained by determining the saturation temperature of the impurities in a sodium bypass, which is led through the orifice of the plugging meter (Fig. 101) at a defined flow rate. In this process, the temperature of sodium is decreased until the saturation concentration of the dissolved impurities is exceeded and they crystallize, plugging the orifice and drastically reducing the flow rate. The temperature at the break in flow rate is defined as the plugging temperature. This is a simple and robust method for the characterization of coolant purity [171]. The plugging temperature is an important input parameter for the operation of the sodium purification systems. The minimum temperature of the cooling systems in operation is maintained at about 20 °C above the plugging temperature.

Figure 102. Hydrogen – tritium measuring device
a) Sodium outlet; b) Flow rate meter; c) Sodium inlet; d) Electromagnetic pump; e) Heat exchanger; f) Thermocouple; g) Nickel tubes

Hydrogen Measuring Device. Hydrogen is detected by its diffusion through a nickel membrane. The device used predominantly is an instrument with a nickel finger system dipping into the sodium (Fig. 102). Hydrogen flow through the nickel membrane is measured with either an ionic getter pump or a katharometer using a carrier gas. The lower limit of detection is ca. 0.01 ppm.

Figure 103. Oxygen meter
a) Reference gas inlet; b) Steel pipe; c) Platinum wire; d) Protective capsule; e) Sodium inlet; f) Thermocouple; g) Solid electrolyte; h) Sodium outlet; i) Screw connection; j) Reference gas outlet; k) Electrical connection

Oxygen Meter. The oxygen dissolved in liquid sodium can be determined by measuring the electromotive force of the oxygen concentration chain:

$$Na_1, [O]_{Na} \left| \begin{array}{c} ThO_2 - Y_2O_3 \\ \text{solid electrolyte} \end{array} \right| \begin{array}{c} O_2 \text{ reference} \\ \text{electrode} \end{array}$$

Various technical models of this measuring device have been developed for use in the plant

(Fig. 103) [172]. The lower limit of detection is < 0.01 ppm.

Carbon Control. The carbon dissolved in liquid sodium is determined by the carbon content of material samples (which either carburize or decarburize) hanging in the sodium. These samples are removed from the sodium system at defined time intervals and analyzed in the laboratory.

4.3.1.2. Chemical Laboratory Analysis

Chemical analyses of the impurities in sodium are employed to measure those impurities that cannot be determined by the operational measuring instruments.

Sodium Sampling. The withdrawal of sodium samples makes great demands on the tightness of the sampling device. Contact with air and the resulting undesirable side reactions must be avoided. Currently, sampling in tube segments [173] or crucibles [174] is used for this purpose. Radioactive samples of sodium from the primary system can be handled only after decay of the ^{24}Na activity (ca. 12 d). Additional contamination of sodium by reaction with air cannot be excluded during transport of the sodium sample from the reactor to the laboratory or during analysis. To avoid reactions with air, preferred devices for the withdrawal of sodium allow direct distilling off of sodium in the sodium cycle [174]. Nonvolatile compounds remaining in the distillation residue are subsequently analyzed [175]. The chemical determination of sodium oxide gives reliable results only if the sodium to be tested is free from particles. If this is not the case, oxygen concentrations measured by this method are usually too high. Volatile compounds can be determined only in sodium samples that have not been distilled. Activation analysis is also employed occasionally.

4.3.2. Control of Cover Gas Purity

The cover gas for sodium surfaces in the cooling systems must have high purity to prevent the interaction of gas impurities with the sodium. The argon cover gas quality is continuously monitored with special gas chromatographs.

4.3.3. Purification of Sodium and Cover Gas

Excessively high concentrations of impurities in sodium can cause malfunctioning of the plant, such as plugging of narrow gaps, corrosion of cladding and structural materials, and transport of radioactivity. Impurities can largely be removed by cold trapping due to their temperature dependent solubility in sodium. A sodium bypass flow enters the cool zone via a regenerative heat exchanger. After the temperature in the cool zone falls below their saturation temperature, dissolved impurities deposit on packings in this zone. A lower operating temperature of 120 °C is technically possible in the cold trap; this corresponds to a residual content of about 1 ppm of oxygen, which is of no importance for corrosion. In addition, packings cause the mechanical deposition of undissolved particles in the cold trap.

Among the radionuclides, ^{131}I and ^{54}Mn (by using nickel packings) can be removed satisfactorily from sodium with the help of cold traps. The nuclides ^{134}Cs and ^{137}Cs can be eliminated by means of a carbon-filled nuclide trap.

Sodium aerosols can be removed from the cover gas with steam traps; fission gases are adsorbed on special activated carbon filters.

4.3.4. Sodium – Water Reactions

During operation of sodium-heated steam generators, the possibility of a sodium – water reaction cannot be completely ruled out. Rates of removal of steam generator materials on the order of several micrometers per second [176] (by a combination of erosion and corrosion) can be determined by experiments in the reaction flame at ca. 1000 °C. With a hydrogen measuring device, even a small leak in the steam generator can be detected early enough to prevent the spread of damage. As soon as a specific critical value for the hydrogen concentration in sodium is reached, the steam generator must be shut off to permit localization and repair of the leak. This alarm value depends on the type and state of the plant.

There are, however, event sequences of a sodium – water reaction that lead to a fast increase of the leakage section by corrosion or even by overheating of neighboring steam generator tubes. In those cases the detection by hydrogen measuring may not be fast enough to trigger the mitigation measures. This is because of the time required for the transport of the reaction products from the leak to the detection device and because of the time it takes to increase the hydrogen concentration in the coolant up to the detection threshold. Acoustic detection devices have been developed in order to analyze the noise spectra of the plant and to identify the specific noise spectrum of the sodium – water reaction. This method eliminates the aforementioned delays. In case of a large leak in the steam generator, the increase in hydrogen pressure is limited by a passive responding pressure relief system (rupture disks). As a back-up, active mitigation measures are triggered (e.g., shut down of the reactor) by detection of the break of the rupture disks.

4.3.5. Sodium Fires

Sodium fires may occur if, as a consequence of a structural material failure (fissure, crack), leakage sodium comes in contact with the ambient atmosphere. Due to the overall plant arrangement and design sodium fires have no radiological consequences and no direct impact on the plant safety. The inherent design principles of sodium plants (low pressure, good material behavior) reduce the risk of sodium leaks. In addition high quality requirements that have been introduced in plant realization, reliable detection systems, and efficient mitigation measures contribute significantly to risk reduction.

Nevertheless, several incidents of this kind occurred in the past. The immediate consequences of sodium fires are energy release, pressure increase in the concerned plant rooms, sodium aerosol release, and chemical reactions with different structures, walls, and system parts. If sodium reaction products are released to the outside of the plant room (which cannot completely be ruled out), the consequences have to be investigated for the plant (e.g., aerosols may be aspired by the decay heat coolers) and for the environment (hazards for human beings, agricultural consequences).

Sodium fires may occur as pool fires, columnar fires, spray fires, or combined fires. The chemical consequences depend on the concerned material, e.g., concrete, steel, insulation material, electrical equipment, and on the temperature produced by the fire event. In pool fires or columnar fires with high leakage sodium flow rates, the temperature is dominated by the operation temperature of the coolant. Another temperature threshold may be the evaporation temperature of the sodium. Accident sequences with high spray fire influence may lead to temperatures higher than 1000 °C. Most of the applied materials and components withstand temperatures in the given order of magnitude only for a limited time. On the other hand the large quantities of sodium aerosols produced by the fire absorb heat radiation and reduce air access to the burning sodium. This limits the propagation of fire. The design goals are:

1) To proof that local destructions in the concerned plant rooms have no consequences for the plant safety. In this framework chemical and thermal resistance of various kinds of material had to be investigated.
2) To investigate consequences of the decay heat removal. This includes investigation of the behavior of the aerosol cloud in the narrow plant environment in order to study the behavior of decay heat removal systems with aerosol loaded atmosphere.
3) To evaluate the aerosol distribution and deposits beyond the plant boundary and potential consequences for humans, plants, and animals.

Particularly the latter aspect has been conscientiously investigated in Germany, France, and Japan. The chemical products of sodium fires are close to those that appear naturally in the environment (all forms of sodium oxide and hydroxide, sodium bicarbonate). The consequences found were not dangerous for the environment, neither theoretically nor practically.

4.3.6. Purification and Decontamination of Components

Components that are wetted with sodium are generally cleaned by using the *steam – nitrogen*

process. In this process the components are heated in nitrogen and then exposed to increasing amounts of steam, which reacts with sodium. Sodium is then withdrawn as an aqueous sodium hydroxide solution. This process is carried out under controlled conditions below 150 °C to avoid corrosion.

For parts with a complicated geometry (narrow gaps, blind holes) the *evaporation of sodium under vacuum* frequently gives better results than the steam – nitrogen method. *Cleaning with alcohols* (methanol, ethanol, isopropanol, etc.) is used only for small parts because of the risk of fire. A higher diethyleneglycol monoethyl ether has been used for this purpose. It is considerably less dangerous than the lower alcohols and can even be heated to improve its cleaning action [177]. Decontamination of the components is always carried out after the removal of sodium. Normal decontamination agents are employed for this purpose. "Soft agents" are used mainly to reduce the danger of corrosion because they are mixtures of mild acids and detergents.

5. Fuel Cycle

5.1. Introduction

In contrast to electricity generation by fossil-fueled power stations, operation of a nuclear reactor requires that the fuel undergoes a cycle in order to make optimum use of the energy carriers, i.e., the fissile isotopes of uranium (^{235}U) and plutonium (^{239}Pu and ^{241}Pu). Spent nuclear fuel elements must be removed from the reactor before all the fissile nuclei contained in them have been fissioned, or "burned," essentially for three reasons: (1) The concentration of fissile nuclei in the fuel decreases due to fission, which lessens the chance for a neutron to hit another fissile nucleus and thus to propagate the fission chain; in other words, the reactivity of the fuel decreases with increasing burnup. (2) Some of the fission product isotopes are strong neutron absorbers, which decrease the fuel reactivity even further. (3) The mechanical strength of the fuel element's structural materials decreases during operation due to radiative, thermal, and hydraulic stresses, thus limiting its mechanical lifetime.

The following rule-of-thumb estimate is aimed at obtaining an idea of the magnitude of the problem. Fresh light-water reactor fuel is enriched to roughly 3.5 % fissile ^{235}U. After a burnup of 35 000 MW · d/t, the fuel, which is now due for removal, still contains ca. 0.9 % ^{235}U, plus ca. 0.6 % fissile plutonium isotopes created by neutron absorption of ^{238}U. The total of ca. 1.5 % fissile isotopes represents more than 40 % of the original fissiles content in the fresh fuel. To make the residual energy carriers available, they must be separated from the spent fuel and recycled into new fuel elements.

Stages of the Fuel Cycle. Figure 104 schematically shows the various stages in the fuel cycle of the light-water reactor. The cycle starts with the *mining* of uranium ore from which uranium is extracted and converted into " yellow cake," U_3O_8. The oxide is further *converted* into uranium hexafluoride (UF_6), a readily volatile compound that is suitable for *isotope enrichment* in a multistage gas separation process such as gaseous diffusion or gaseous centrifugation. In this stage, the ^{235}U isotopic concentration is enriched from its natural 0.72 % to about 3 – 3.5 %. The depleted uranium fraction contains ca. 0.25 % ^{235}U and is excreted from the cycle for eventual reuse in a breeder reactor. Enriched uranium hexafluoride then passes to the *fuel element fabrication plant* where it is converted into uranium dioxide (UO_2), which is pelletized, filled into Zircaloy tubes, and assembled. The fuel assemblies are loaded into the reactor for power generation by neutron-induced fission of the fissile isotopes.

At the end of their useful life, the spent fuel assemblies are unloaded from the reactor and transferred to an on-site storage pond for intermediate storage, or "cooling". This allows the radioactive fission products to decay according to their specific half-lives. The short-lived fission product isotopes, in particular, decay totally during on-site storage, which reduces both the radiation level and the decay heat output substantially. The "cooled" fuel assembly is then loaded into an air-cooled, shielded container and transported to the chemical reprocessing plant, where it is cooled further either under water after unloading into a storage pond, or by air cooling in a dry storage facility. The total cooling period of LWR fuel elements before reprocessing is usu-

Figure 104. The LWR fuel cycle

ally between three and seven years because a fast recycle of the fissile materials is not essential in the LWR.

The main task of the *reprocessing plant* is to separate and purify the residual energy carrier materials (uranium and plutonium) from the fission products. This is done by the PUREX process, which yields the metal values in the form of concentrated solutions of their nitrates, namely $UO_2(NO_3)_2$ and Pu $(NO_3)_4$, respectively. At the same time the bulk of the fission products are collected as a concentrated "high-active waste" (HAW) nitrate solution and transferred to a *waste solidification plant* and then to a *final storage site*. The uranium product is recycled for conversion and reenrichment, whereas the plutonium product is recycled for conversion and fabrication into a (U, Pu)O_2 mixed-oxide (MOX) fuel.

Fuel Consumption of Different Types of Fuel Cycles. The net effect of the LWR fuel cycle is illustrated in Figure 105 [178] which details the consumption of uranium for the generation of 1 gigawatt-year (GW · a) of electric energy (1 GW · a is roughly the electrical energy produced by a standard 1300-MW power reactor during one year of operation, if an overall load factor of ≈ 80 % is assumed). The upper line illustrates the "throwaway" operation; i.e., spent fuel is not reprocessed and recycled, but instead is disposed in the deep underground as a radioactive waste material. In this case, ca. 205 t of natural uranium is required, which must first be converted into 37 t of 3 % ^{235}U-enriched uranium fuel. The balance of 168 t of depleted uranium is left behind as a waste material that cannot be used further in thermal reactors. Although it could be used in fast breeder systems, these cannot be started because the plutonium needed is not recovered in the throwaway operation mode. Of the fuel uranium, 1.2 t is fissioned in the reactor to produce 1 GW · a of electric energy; the spent fuel, composed of roughly 35 t of uranium (residual enrichment 0.9 %), 0.3 t of plutonium (65 % fissile), and 1.2 t of fission products, is wasted.

The middle line of Figure 105 illustrates the light-water reactor with fuel recycle; the figures given describe the recycle equilibrium state. In this case, the natural uranium requirement for 1 GW · a of electric energy is 120 t, a saving of ca. 40 % compared to the throwaway case. Again, a major part of the material is lost in the form of depleted uranium, but the only other ma-

Figure 105. Uranium consumption for generation of 1 GW · a of electricity by light-water reactors with or without fuel recycle, and by fast breeder reactors with inherent fuel recycle [178]

terial loss is the 1.2 t of fission products produced during reactor operation. Both the spent fuel uranium and the plutonium produced by neutron absorption are recycled for additional energy production. If needed, the recovered plutonium can be used as the starting fuel for fast breeder reactors. In this case the stock of depleted uranium could be used as the blanket material for breeding new fuel.

The fuel-saving potential of the fast breeder reactor is illustrated in the lower line of Figure 105. The enormous superiority of this reactor type in terms of fuel economy is due to the fact that it "breeds" more fissile plutonium from nonfissile uranium-238 than it consumes for fission and energy production (see Chap. 4). Consequently, no external supply of fissile isotopes is required after the FBR has reached its recycle equilibrium, and the only material to be replaced is the uranium-238 that is converted into plutonium-239 and higher isotopes. In equilibrium, with inevitable recycle losses taken into account, this reload requirement is roughly 1.5 t of natural or depleted uranium per gigawatt-year of electric energy, less than 1 % of the throwaway LWR. The FBR generates fewer fission products than the LWR, ca. 1 t per GW · a, because it produces steam at a distinctly higher temperature (ca. 500 °C vs. 280 °C) and consequently achieves a higher thermodynamic conversion efficiency (ca. 40 % vs. 32 %). The excess production of plutonium ("breeding gain")/given as 0.3 t/GW · a in Figure 105, but adjustable within wide limits by varying reactor design details, can be used for the start-up of additional FBRs if required. The FBR fuel cycle (see Fig. 106) eliminates the need for uranium enrichment and, hence, the loss of depleted uranium, which is primarily responsible for the high uranium demand of thermal reactor systems.

Nevertheless, with the present oversupply and consequent low prices of uranium, the cost of electricity generation is more favorable for the light-water reactor than for the fast breeder reactor. A French estimate claims a cost difference of some 15 % for the two under current uranium price conditions [179]. This difference in cost is partly due to the reactor itself but also to the higher cost of both FBR fuel element fabrication and spent fuel reprocessing. For the long term, therefore, the question of uranium resources and its relation to demand remains to be answered.

Uranium Resources. Surprisingly enough, uranium is not a particularly rare element. Its average concentration in the earth's crust is 2.1 g/t

Figure 106. The FBR fuel cycle

[180], making it more abundant than metals such as cadmium (0.15 g/t) or silver (0.1 g/t). In primary rock, its concentration is generally much higher in acid rock such as granites (4.8 g/t) than in basic rock such as basalts (0.6 g/t). Its average concentration in seawater is 0.3 mg/m^3. The total amount of uranium in the earth's crust down to a depth of 20 km has been estimated as 5×10^{13} t, the ocean waters are estimated to contain 5×10^{9} t. Unfortunately, however, due to its chemical properties, uranium does not normally tend to accumulate in large deposits. As a result, most of it is more or less evenly distributed over the earth's surface at the above-mentioned concentration, which obviously does not warrant economical recovery.

The very small fraction of terrestrial uranium that occurs in deposits concentrated enough, large enough, and accessible enough, to make recovery economical, is referred to as "uranium resources." These are quite well-known because uranium is easily detected and analyzed by virtue of its radioactive properties, and they are listed in *Uranium Resources, Production and Demand*. This report, published jointly by the Organization for Economic Cooperation and Development (OECD) and the International Atomic Energy Agency (IAEA) and known as the " Red Book", is periodically updated, the latest available edition at the time of writing having been issued in 1989 [181]. Based on national reports provided by the participating countries, it presents data for the (then) noncommunist world, referred to as the "world outside centrally planned economic areas" (WOCA). Unfortunately, figures from the (then) communist countries, notably the former Soviet Union, China, former East Germany, and former Czechoslovakia, which presumably have major resources, are not available thus far, but this situation can be expected to change in the future. Nevertheless, the accessible data draw a picture clear enough to allow conclusions to be made.

Categories of Resources. The Red Book defines, in decreasing order of certainty of knowledge, four categories of resources:

Reasonably Assured Resources (RAR) refers to uranium that occurs in known mineral deposits of delineated size, grade and configuration such that the quantities which could be recovered within the given production cost ranges with currently proven mining and processing technology, can be specified. Estimates of tonnage and grade are based on specific sample data and measurements of the deposits and on knowledge of deposit characteristics. Reasonably Assured Resources have a high assurance of existence.

Estimated Additional Resources–Category I (EAR-I) refers to uranium in addition to RAR that is inferred to occur, mostly on the basis

of direct geological evidence, in extensions of well-explored deposits or in deposits in which geological continuity has been established but where specific data, including measurements of the deposits, and knowledge of the deposits' characteristics are considered to be inadequate to classify the resource as RAR. Estimates of tonnage, grade and cost of further delineation and recovery are based on such sampling as is available and on knowledge of deposit characteristics as determined in the best known parts of the deposit or in similar deposits. Less reliance can be placed on the estimates in this category than on those for RAR.

Estimated Additional Resources– Category ***II*** (EAR-II) refers to uranium in addition to EAR-I that is expected to occur in deposits for which the evidence is mainly indirect and which are believed to exist in well-defined geological trends or areas of mineralisation with known deposits. Estimates of tonnage, grade and cost of discovery, delineation and recovery are based primarily on knowledge of deposit characteristics in known deposits within the respective trends or areas and on such sampling, geological, geophysical or geochemical evidence as may be available. Less reliance can be placed on the estimates in this category than on those for EAR-I.

Speculative Resources (SR) refers to uranium, in addition to Estimated Additional Resources–Category II, that is thought to exist, mostly on the basis of indirect evidence and geological extrapolations, in deposits discoverable with existing exploration techniques. The location of deposits envisaged in this category could generally be specified only as being somewhere within a given region or geological trend. As the term implies, the existence and size of such resources are speculative.

In addition, the Red Book classifies resources according to their estimated recovery cost into three categories: (1) up to \$ 80/kg of uranium, (2) \$ 80 – 130/kg of U, and (3) \$ 130 – 260/kg of U. Practically all reported resources of types RAR and EAR-I are in the lower cost categories (1) and (2). In contrast, only a limited number of national reports have been prepared for speculative resources, and these were either for recovery cost categories up to \$ 130/kg and \$ 130 – 260/kg or, in some cases, did not differentiate at all among cost levels.

Furthermore, the Red Book defines the combined RAR and EAR-I resources of recovery cost below \$ 130/kg of U as *known conventional resources*, whereas the combined EAR-II and SR categories are termed *undiscovered conventional resources*, indicating the degree of confidence that the respective estimates deserve. All uranium presently mined is in the cost range below \$ 80/kg of U, and in fact far below this mark, as spot market prices (not cost) of roughly \$ 26/kg of U (June 1989) [182] indicate.

From Table 48, a total of ca. 3.4×10^6 t of known conventional uranium resources in 1989 can be inferred for WOCA [181]. Estimates given for the high cost range (\$ 130 – 260/kg U) of RAR and EAR-I were a total of roughly 0.6×10^6 t (RAR: 0.400×10^6 t; EAR-I: 0.185×10^6 t) and, when included in the account, do not essentially change the picture. Undiscovered conventional resources (Table 49) for production costs up to \$ 260/kg, as described in national reports, were between ca. 8.1 and 9.5×10^6 t of uranium, and mainly in the "speculative" category, but only a few national authorities have submitted speculations on undiscovered resources. However, in the International Uranium Resources Evaluation Project (IUREP) carried out by OECD and IAEA in 1977 and revised in 1983, the range of speculative resources at recovery costs up to \$ 130/kg of uranium for 169 countries in WOCA was believed to be between 6.4 and 16×10^6 t of uranium, with the most likely range between 9.6 and 12.1×10^6 t [181].

Table 48. Known conventional resources (in 10^6 t of uranium) for the world outside centrally planned economic areas (WOCA), January 1989 [181]

Resource	Cost range		Total
type ∗	≤ 80/kg U	\$ 80 – 130/kg U	≤ \$ 130/kg U
RAR	1.546	0.655	2.201
EAR-I	0.773	0.391	1.164
Total	2.319	1.046	3.365

∗ RAR = reasonably assured resources; EAR-I = estimated additional resources– category I.

Unconventional Resources. In addition to the conventional resources considered so far, a total of roughly 7×10^6 t of uranium in unconventional (i.e., byproduct) resources has been reported in a few national reports evaluated in the Red Book [181]. By far the most important source in this category is uranium occurring in

marine phosphate rock deposits, notably those in Morocco, where a total of 6.5×10^6 t of uranium is claimed to exist at an average grade of 120 g of uranium per tonne. This uranium might become economically recoverable as a byproduct, i.e., at a production rate determined by the rate of phosphoric acid production from such material, provided that the extra recovery cost can be reduced to competitive levels.

Table 49. Undiscovered conventional resources (in 10^6 t of uranium) for WOCA, January 1989 [181]

Resource	Cost range		Total
type ∗	≤ \$ 130/kg U	\$ 130 – 260/kg U	≤ \$ 260/kg U
EAR-II	1.686	0.649	2.335
SR			5.813 – 7.113
Total			8.148 – 9.448

∗ EAR-II = estimated additional resources– category II; SR = speculative resources.

Uranium Resources and Demand–Future Trends. To relate resources and demand, a very simple approach is made here on the following basis: (1) The resource base is restricted to known conventional resources (3.4×10^6 t U for WOCA in 1989). This condition seems justified in view of the high degree of uncertainty regarding the existence, size, and recovery costs of undiscovered resources, and of the presumably limited production rate of uranium from byproduct resources. (2) Nuclear energy production in WOCA is assumed to increase linearly from its present annual level of ca. 165 GW · a (OECD 1989 [183]; the OECD figure is essentially the same as that for WOCA) to 330 GW · a per year, within 25 years (i.e., with the same average rate as in the first 25 years of nuclear power utilization), and then to remain at this level. This is probably a rather pessimistic assumption, in view of the expected worldwide increase in energy demand and the anticipated requirement limit the combustion of carbon-based fossil fuels because of their environmental impact ("greenhouse effect"). (3) No limitations in uranium availability due to restricted or delayed construction of mining, recovery, enrichment, fuel fabrication, fuel reprocessing, or waste treatment and disposal facilities are expected. With these conditions and the data given in Figure 105, the operational range of WOCA's known conventional resources would be estimated to be:

light-water reactors operated with fuel throwaway	ca. 60 years
light-water reactors operated with fuel recycle	ca. 90 years
fast breeder reactors	ca. 6800 years

For a more reliable forecast, much better knowledge of future trends in world energy demand, supply structures, resource availability, production capacities, prices, and political developments is obviously required. Despite the inherent imponderables many scenarios have been developed and analyzed, and the results have been presented and discussed at World Energy Conferences which are held periodically as an international forum on energy matters. The majority of such scenarios, at least the more serious ones, arrive at results surprisingly close to the primitive rule-of-thumb approach presented here; see, e.g., Beckurts et al. [184] who, on the basis of a very detailed analysis, arrive at an operational range of < 50 years for LWRs without fuel recycle.

The conclusions that must be drawn from this situation are, in principle, self-evident. At the present stage of technical development, human energy requirements are predominantly satisfied by the combustion of carbon-based fossil fuels and by the fission of heavy nuclei. Both are limited in their operational range to at best a few centuries, with the exception of nuclear fission in fast breeder reactors which has the potential to cover several millennia or more if low-grade uranium resources become economical for this low-consumption technique. Other available technologies will contribute only small increments to the world's growing energy demand. As long as no fundamentally new large-scale energy generation process is developed to the stage of technical and economic application, nuclear fission in fast breeder reactor systems is the only long-term energy source available to humans (where "long-term" means, e.g., $> 10^3$ years). Therefore, wasteful techniques must not be used in the consumption of uranium. This is the reason why legal provision has been made in a number of countries to prevent the waste of fissile raw materials. The German Atomic Law [185], for example, incorporates the so-called reutilization requirement (*Wiederverwertungsge-*

bot), which stipulates that spent nuclear material containing fissile residues must be recycled for reuse as long as technically possible and economically feasible.

Feasibility of the Fuel Cycle. The technical feasibility of all stages of the nuclear fuel cycle is demonstrated by the successful operation of large-scale industrial facilities in various countries, with one important exception. Permanent storage facilities for unretrievable disposal of high-level radioactive waste products in deep geologic repositories have not so far been put into operation; instead, these are still in the research or planning stage, while HAW materials are being stored in interim surface storage plants. Nevertheless, permanent disposal facilities are expected to be built and operated successfully.

Fuel Cycle Economics. What remains to be answered is the question of fuel cycle economics. For this purpose the results of a very careful analysis in 1985 by the OECD Nuclear Energy Agency (NEA) Working Group on the Economics of the Nuclear Fuel Cycle [186], and an update based on French industrial experience [187], are discussed. An important feature of the OECD/NEA model is that the complete reactor lifetime, not a single reload, is considered, and that the costs and payment schedules for all parts of the fuel cycle are precisely defined.

Table 50 presents a breakdown of the fuel cycle reference costs for pressurized-water reactors operated with or without fuel recycle, as evaluated by the OECD/NEA [186]. Total fuel cycle reference costs were estimated to be 8.56 millidollars (or "mills", 1 m\$ = 0.1 cent) per kilowatt-hour for fuel recycle and 7.78 m\$/kW · h for the throwaway case, i.e., a cost advantage of 0.78 m\$/kW · h, or 10 %, for the latter. However, the absolute value of 0.78 m\$/kW · h makes clear that this cost difference is marginal compared to the total electricity generation cost, which is on the order of 50 m\$/kW · h, being determined by the investment and operating costs of the reactor itself which account for about 80 % of the total costs of nuclear electricity generation.

To account for uncertainties in the assumptions made for different fuel cycle components and parameters, a thorough *sensitivity analysis* was also carried out. The total fuel cycle costs were found to be highly sensitive to uranium prices but only slightly sensitive to major changes in the costs of uranium conversion, fuel transport and storage, reprocessing, and waste treatment and disposal. Based on sets of reasonable variations of parameters, a "likely range" of fuel cycle costs was evaluated to be between 7.1 and 10.4 m\$/kW · h for fuel recycle and between 6.3 and 9.7 m\$/kW · h for the throwaway option.

A reevaluation by Couture et al. [187] using the OECD/NEA methodology, but applying real reprocessing costs as experienced by the French COGEMA (Compagnie Générale des Matières Nucléaires), has led to total PWR fuel cycle costs of 7.6 m\$/kW · h for fuel recycle and 8.2 m\$/kW · h for the throwaway case, i.e., a slight cost advantage of 0.6 m\$/kW · h (8 %) for recycle. The COGEMA values are well within the "likely cost range" as determined by the OECD experts, and the cost difference is, in absolute terms, again marginal. Any increase of the (highly sensitive) uranium price beyond the present low level will, however, shift the cost advantage further in favor of fuel recycle. Moreover, progress in recycle technologies with inherent cost reductions (for which ample room exists) will have the same effect.

Conclusions. Based on these facts, the following rules can be formulated for a responsible application and management of nuclear power, taking into account both the present state of, and the long-term prospects for, the uranium supply:

1) Operation of nuclear power reactors with permanent disposal of the spent fuel is a wasteful technique that does not correspond to the state of scientific, technological, and economic development and is therefore inadequate. Specifically, this mode of operation would presumably limit the utilization of nuclear energy to less than a century because it would prevent the eventual transition to fast breeder technologies.
2) For the present period of high uranium supply and low prices, the operation of thermal power reactors with fuel recycle is adequate as long as this is more economic than the use of fast breeder reactors.
3) Provided no fundamentally new large-scale energy source can be developed and employed in time, the operation of fast breeder

reactors will eventually become economically competitive due to a decrease in uranium supplies and consequent increase in prices. Over the long term, the application of fast breeder recycle techniques will constitute an absolute necessity under the circumstances assumed because of its very low uranium demand.

5.2. Uranium Production, Conversion, and Enrichment [188–190]

In contrast to other primary energy sources such as coal, natural gas, and petroleum, uranium is currently used only as a fuel for the production of electricity in nuclear power plants. Future nuclear plants might generate not only electrical power but also process heat for the production of secondary energy sources, such as methane obtained by coal gasification. One special application of nuclear energy is the propulsion of ships and submarines.

5.2.1. Occurrence and Classification of Deposits

The continental crust contains relatively high concentrations of uranium. The average abundance is 2.1 ppm. Naturally occurring uranium is a mixture of three isotopes: ^{238}U (99.28 %), ^{235}U (0.71 %), and ^{234}U (0.006 %). Geochemically, uranium is a lithophilic element, as shown by its high affinity for oxygen. Consequently, uranium has the ability to form many complexes that are stable in aqueous solution over wide pH ranges. This ability is responsible for the transport of uranium and its mobility in geologic formations.

Uranium mineralization occurs in nearly all rocks of the earth's crust. Uranium ore deposits can be classified in seven main types with a number of subtypes. Three principal types are of particular economic importance: the unconformity, conglomerate, and sandstone types. Deposits of these types are associated predominantly with certain epochs in the earth's history and often occur in geographic provinces (see Table 51).

The great economic importance of *unconformity deposits* is due to the size of individual deposits and their often very high average ore grade (2 – 10 % U_3O_8, sometimes up to 15 % U_3O_8). These are the most significant deposits at present, accounting for some 27 % of currently known world reserves and more than 30 % of world production. The latter figure will increase as lean-ore deposits such as Canada's Elliot Lake region become exhausted or uneconomical.

Conglomerate deposits are the oldest known deposits. They are mined in only two regions, i.e., the Witwatersrand area in South Africa and the Elliot Lake area in Canada, Uranium is the

Table 51. Uranium ore deposits

Type	Characteristics	Age	Example	Mean U_3O_8 content, %
Unconformity	unconformity between metamorphic rocks (basement) and nonmetamorphic clastic sediments; monomineralic, polymetallic	Proterozoic	Key Lake, Canada	2.5
			Cigar Lake, Canada	10.0 – 14.0
			Jabiluka, Australia	0.30
			Ranger, Australia	0.25
Conglomerate	gold – pyrite-bearing quartz conglomerates	Late Archean – Early Proterozoic	Witwatersrand, South Africa	0.025 – 0.05
			Elliot Lake region, Canada	0.1 – 0.15
Sandstone	stratabound ore bodies; permeability-dependent ore bodies unconformable with beds; basal channel casts	Upper Paleozoic, Mesozoic	Colorado Plateau, United States	0.1 – 0.3
			Grants Mineral Belt, United States	0.1 – 0.3
			Wyoming and Texas basins, United States	0.1 – 0.3
			Akouta, Niger	0.5

primary mineral product in Canada, whereas in South Africa it is a byproduct of gold mining. Because of its low ore grade (0.02 – 0.15 % U_3O_8) the importance of this deposit type will continue to decline; its share is expected to fall from 19 % of world production in 1989 to barely 17 % in 1991.

Sandstone uranium deposits are the most common worldwide, occurring in virtually every epoch of geologic history. At the beginning of the 1980s, this type accounted for some 40 % of world reserves. With the falling price of uranium, the significance of these deposits has decreased sharply because of their low ore grades (0.1 – 0.5 % U_3O_8). Sandstone deposits constituted about 20 % of the recoverable reserves worldwide at the end of 1988 (up to $ 80/kg U) and represented a similar share of world production. The drastic cut in production from these deposits is particularly marked in the United States. More than 40 mines were operating in the Grants Minerals Belt at the end of the 1970s, but conventional uranium mining in sandstone deposits has since come to a complete halt. The last operating mine, Mt. Taylor, closed in late 1989.

Other deposit types are currently of secondary importance in overall production. This situation may change if larger and more economic deposits are discovered. One example is the Roxby Downs deposit in Australia, which is a polymetallic iron ore deposit with economically exploitable quantities of copper, uranium, gold, and silver. The deposit is a brecciated ore body of the Proterozoic age, consisting mainly of granite fragments. Intensive exploration in regions not yet heavily examined may increase the significance of other deposit types.

5.2.2. Production

Prospecting and Exploration. The search for possible deposits (*prospecting*) begins with the evaluation of large areas in accordance with the most recent findings of earth sciences. Geophysical and geochemical methods, in particular, have increased in importance over the past 20 years for prospecting purposes. When an area with large anomalies has been localized, it is then *explored*; i.e., the exact size and extent of the ore bodies are determined, along with the petrographic and mineralogic compositions. Detailed exploration ends with a *feasibility study*, which considers the economics of recovery. Once the feasibility study has been completed and assessed, a decision on implementing the project is made. The time required from prospecting to the start of mining and ore processing is 10 – 15 years: prospecting requires 3 – 5 years; exploration 2 – 3 years; and the approval and construction phase 5 – 8 years [191]. The lifetime of a project, i.e., the actual mining and ore processing may vary from a few months to several decades.

Processing. Because of their relative abundance, only 12 of more than 120 naturally occurring uranium minerals are mined and processed into commercial uranium concentrate (see Table 52).

Uranium ore from the mine is *presorted* by composition into uranium-bearing ore and bar-

ren rock. Ore separation is basically performed to reduce operating costs. At most ore concentration plants, presorted uranium ore is milled in crushers to obtain fine ore with grain sizes < 10 mm. A subsequent grinding step might follow to yield a fine powder.

Extraction includes leaching of crushed uranium ore with acid (sulfuric, hydrochloric, nitric, or phosphoric) or alkaline solvents (carbonates or hydrocarbonates). The choice of solvent depends mainly on the chemical composition of the uranium mineral and the accompanying rock.

After leaching, solids and leach liquor are separated by *flocculation* and *filtration*. The uranium is precipitated from the solution, usually as a diuranate.

The uranium concentrate obtained in this way is called " yellow cake" because of its color. It generally contains > 70 % uranium.

The time required for subsequent purification, refining, enrichment, and fuel fabrication steps varies greatly and depends on many factors such as the reactor type and the stockpiling policies of the power plant operator.

A rough overview of typical times is given below:

From ore preparation to U_3O_8 (yellow cake)	1 – 6 months
From U_3O_8 concentrate to UF_6	2 – 6 months
From UF_6 to enriched UF_6	6 months
From enriched UF_6 to UO_2	3 months
From UO_2 to fuel assembly	3 – 6 months
From fuel assembly to reactor fueling	0 – 3 months

5.2.3. Output and Demand

Uranium *production* rose steadily from 1974 to 1980. A consolidation phase followed in 1980 to 1982; since that time, output in the Western world mining countries has declined steadily (see Table 53). The lowest level was reached in 1990. The decline in output between 1980 and 1990 resulted from shutdowns of uneconomical uranium mines, political sanctions, and reduced demand. Output will again increase slightly until 2000, but will not reach the 1980 high.

In 1983, uranium *demand* for nuclear power plants exceeded production for the first time. The shortfall has since been made up from power plant operators' existing inventories, but this resource will exist for only a limited time.

Set against the cumulative reactor demand of some 560 000 t of uranium between 1990 and 2000 are reserves of 2.3×10^6 t U (categories RAR and EAR-I recoverable up to \$ 80/kg U); not included are reserves in China and the Eastern Bloc. Even if nuclear energy were to grow faster than expected, a dependable supply would be available until 2030.

5.2.4. Conversion

Conversion is the intermediate process between yellow cake production and enrichment. To in-

crease the ^{235}U content in natural or reprocessed uranium, a volatile uranium compound is required in the enrichment step. Uranium hexafluoride (UF_6) is the only uranium compound that is suitable for enrichment because of its thermal stability and relatively high volatility. All current enrichment processes, therefore, employ uranium hexafluoride.

Uranium hexafluoride is produced from uranium concentrate by two processes, wet and dry. A schematic of the conversion processes is given in Figure 107.

Wet Process. In the wet or aqueous process, the uranium concentrate is first dissolved in nitric acid and purified by solvent extraction with tributyl phosphate (TBP), diluted with kerosene. Treatment with ammonia precipitates ammonium diuranate [$(NH_4)_2U_2O_7$, ADU]. This product is dried, calcinated, and reduced to uranium dioxide with hydrogen. In another process, the solution remaining after solvent extraction is evaporated to obtain uranyl nitrate hexahydrate [$(UO_2)(NO_3)_2 \cdot 6\,H_2O$, UNH]. The UNH is thermally decomposed to uranium trioxide, which is also reduced to uranium dioxide with hydrogen.

The uranium dioxide is then converted to uranium hexafluoride by reaction with hydrogen fluoride (hydrofluorination) and oxidation with elemental fluorine.

Dry Process. In the dry process, the uranium concentrate is reduced directly to uranium dioxide with hydrogen in a fluidized-bed reactor. The next steps are reaction with hydrogen fluoride and oxidation with fluorine as in the wet process, except that the hexafluoride product is less pure. Residual impurities are removed by fractional distillation. The end product, however, has a higher purity than that produced from the wet process.

For technical reasons, a conversion plant can be operated at only 80 – 90 % of design capacity. Even so, the capacity of existing plants is sufficient to meet international demand for years to come (see Table 54). Although installed conversion capacity is around 54 000 t of uranium (plants in Eastern Europe are not included) the demand for conversion of natural uranium in 1990 was 42 300 t U and will increase to ca. 47 500 t of uranium in 2000.

Table 54. Conversion plants in WOCA

Country	Plant	Uranium capacity, t	Process
United States	Metropolis	12 700	dry
	Sequoyah	9 090	wet
France	Pierrelatte	14 000	wet and dry
United Kingdom	Springfields	9 000	wet
Canada	Port Hope	9 000	wet
Total		53 790	

In addition to large-capacity plants in the United States, France, Canada, and the United Kingdom, whose products are sold internationally, smaller plants serve primarily domestic needs or are intended to do so in the future (Brazil, South Africa, Japan, and India).

Figure 107. Schematic diagram of conversion processes [193]

5.2.5. Enrichment

Natural uranium contains only 0.71 % of the isotope ^{235}U. This fraction must be increased to > 2.5 % to sustain a chain reaction in light-water reactors. Modern power reactors use uranium with an enrichment up to 5.0 %. Large-scale uranium enrichment is currently achieved by the gaseous diffusion and gas centrifuge processes. About 90 % of the enrichment plants in the Western world employ gas diffusion. The nozzle separation (jet nozzle) process developed in Germany has also come into full-scale use. The laser separation process is still in the developmental stage; a demonstration plant is not expected to be in operation before the mid-1990s.

The gaseous diffusion, gas centrifuge, and nozzle separation processes have in common a gas mixture feed consisting of $^{235}UF_6$ and $^{238}UF_6$, which is inlet into a medium where it is separated into two partial streams that are discharged. The product stream is a gas fraction enriched in $^{235}UF_6$, whereas the tails stream is depleted in $^{235}UF_6$. Along with $^{238}UF_6$, the tails stream also contains $^{235}UF_6$, the so-called tails assay.

Centrifuge Process. In the centrifuge process, the $^{235}UF_6$–$^{238}UF_6$ stream enters into a rotating centrifuge (see Fig. 108 A). The heavier $^{238}UF_6$ molecules collect at the outer wall of the centrifuge, whereas the lighter $^{235}UF_6$ molecules collect near the axis where they are withdrawn as an enriched product stream. The separation factor of a centrifuge depends on the peripheral velocity and the length of the centrifuge tube. Industrial centrifuges are therefore tubes operated in supercritical rotation. A counterflow is generated inside the centrifuge to enhance the isotope separation. Even so, the separating efficiency is so low that many centrifuges must be linked in a cascade. To achieve a 3 % enrichment requires a series of 10 to 15 centrifuges.

Diffusion Process. In the diffusion process, gaseous uranium hexafluoride is pumped under high pressure through fine-pored membranes (barriers). The membrane material must be mechanically strong to withstand the large pressure difference and chemically resistant to UF_6 (see Fig. 108 B). The lighter $^{235}UF_6$ diffuses through the barriers more rapidly and collects on the downstream side. As in the centrifuge process, a single separation step is insufficient. To effect a 3 % enrichment, separation must be repeated 1000 to 1500 times in barrier cascades.

The centrifuge separation process has the advantage of a much lower power consumption in comparison to gaseous diffusion.

Jet Nozzle Process. The jet nozzle process uses primarily centrifugal forces for isotope separation. A gas mixture consisting of 4 % UF_6 and 96 % helium is passed through a slot-shaped nozzle. The gas stream is deflected at an outer wall by 180°. The heavier $^{238}UF_6$ particles collect at the outer wall, whereas the lighter $^{235}UF_6$ particles are deflected with the gas stream (→ Air Classifying, Chap. 4.2.2.). This separation process is increased by a peeling cutter.

Laser Processes. Much effort is being put into the development of a laser process for isotope separation. The *AVLIS* (*atomic vapor laser isotope separation*) *process* developed in the United States and France is based on slight differences in the absorption spectra of various isotopes of the same element. A stream of elemental uranium vapor is irradiated by a laser beam and the ^{235}U isotopes are selectively photoionized. The ^{235}U isotopes are then separated electromagnetically from the other uranium isotopes.

Developmental work on *molecular laser isotope separation (MLIS)* continues in Germany.

In addition to the United States, France, the former Soviet Union, and the three Urenco plants (in The Netherlands, the United Kingdom, and Germany) are the most important vendors of enrichment services (see Table 55). Other plants, usually with smaller capacities, serve domestic consumers.

5.3. Fabrication of Fuel Elements

5.3.1. Fuel Assemblies for Light-Water Reactors [195], [196]

5.3.1.1. Functions of Fuel Assemblies

Of a number of material combinations suitable for fuel assemblies in light-water reactors (uranium metal with aluminum cladding is an early example), one has become the standard: uranium dioxide (UO_2) fuel in the form of a stack of cylindrical pellets surrounded by a cladding

of Zircaloy. A fuel rod or pin, up to 5 m long and 9.5 – 11 mm in diameter, performs two contrasting functions. The rod must offer the least possible resistance to the release of heat produced by fission, but it must also provide total retention of fission products over its entire lifetime in the reactor (up to 4 (in PWR) and 6 (in BWR) years). Although off-gas systems of light-water reactors are designed to handle the amount of fission products formed in reactor operation with up to 1 % defective fuel rods, fuel-rod failure ratios of only ca. 0.001 % are common. The economics of the fuel assembly is governed largely by the burnup achievable at low defect rates. Since the 1970s the reload-batch discharge burnup has been steadily increased to 45 – 50 MW · d/kg for PWR (i.e., for a reload batch size of ca. one-fourth of the fuel assembly per year) and 40 – 45 MW · d/kg for BWR. This increase is a result of the development of cladding material that is more resistant to waterside corrosion, more dimensionally stable pellet ceramic structures, and the use of integral burnable absorbers such as Gd_2O_3.

With ^{235}U enrichments up to 5 wt % (current fabrication limits) burnups of 60 – 65 (PWR) and 55 – 60 (BWR) MW · d/kg are realistic targets for the next 1 – 2 decades [197].

5.3.1.2. Raw Material for Nuclear Fuel

Virtually the only raw material needed for the manufacture of nuclear fuel is uranium hexafluoride because light-water reactors contain enriched uranium and industrial enrichment processes operate with gaseous uranium hexafluoride. Uranium from reprocessing plants is available as uranium oxide, U_3O_8 or UO_2. If it is reused in LWRs it must either be reenriched or blended with medium or high enriched uranium (MEU or HEU). This material is at present available from the disposal of surplus weapon HEU due to nuclear disarmament treaties or from the disposal of surplus amounts of MEU (20 – 23 % ^{235}U) used for military ship reactors. Reenriched material arrives at the fuel fabrication process in the form of uranium hexafluoride. When chemically contaminated scrap and waste are produced in the fabrication process, their uranium content is recovered by extraction as $(UO_2)(NO_3)_2$ solution and recycled in this form.

5.3.1.3. Conversion Processes → Uranium, Uranium Alloys, and Uranium Compounds, Chap. 6.3.10.

Conversion in this case means the transformation of gaseous uranium hexafluoride to sinterable uranium dioxide. The amount of uranium dioxide produced worldwide is some 10 000 t/a. There are four competing conversion processes [198–200]. The demands made on these processes are as follows: they must be simple, quantitative, and able to be carried out in simple apparatus with the smallest possible amount of harmful byproducts. The uranium dioxide must have nuclear-grade purity and must contain the smallest possible amount of residual fluorine (because as little as 20 ppm fluorine in uranium dioxide can cause severe cladding damage). It must also have a consistent processability; i.e., it must be sinterable and free-flowing. The latter property allows quick and uniform mold filling and ensures the structural homogeneity of the sintered material, with no perceptible structure of the original UO_2 grains [201].

From the process-engineering standpoint, the conversion should be assessed in conjunction with the subsequent fabrication of uranium dioxide sintered material, because extra effort to prepare the powder for compaction can be offset against extra effort in the chemical process.

Wet Process. At first, gaseous ammonia or hydrogen peroxide was used to precipitate uranium from an *aqueous nitrate solution* because this operation, which yields ammonium diuranate (ADU), $(NH_4)_2U_2O_7$ and $UO_4 \cdot 2\,H_2O$, also removes impurities. The product compounds are converted by heating to UO_3 and U_3O_8, respectively, and either of these can be quantitatively reduced to uranium dioxide with hydrogen at 600 °C. These processes give better product with respect to residual fluorine content and the sinterability than direct hydrolysis of UF_6 (see below):

$$UF_6 + 2\,H_2O \rightarrow UO_2F_2 + 4\,HF$$

$$UO_2F_2 + H_2O \rightarrow UO_3 + 2\,HF$$

or precipitation of ADU from aqueous UO_2F_2-solution.

Ammonium Uranyl Carbonate Process. A free-flowing powder with disappearing particle structure was formerly produced only in the ammonium uranyl carbonate (AUC) process [202]. In this process, originally developed by NUKEM and now still employed by ABB-Atom, KNFC (Korea) and INB (Argentina), uranium hexafluoride is introduced into an ammonium carbonate solution through nozzles, along with ammonia and carbon dioxide. In contrast to ADU, which forms a very fine-grained precipitate when ammonia alone is added, a precipitate of tetraammonium tricarbonato dioxouranate $[(NH_4)_4 \cdot UO_2(CO_3)_3]$ is formed along the pH gradient (pH 5.5 – 7.5) in the reaction zone. Tetraammonium tricarbonato dioxouranate crystallites of well-defined size (around 40 µm) precipitate when more ammonium carbonate is added (in the pH range between 5.5 and 7.5). This process and the final pH value can be controlled to some extent through the solution temperature and the $NH_3 - CO_2$ ratio. The very uniform salt precipitate is separated from the mother liquor on rotary disk filters, and the

salt cakes are treated with methanol to remove adherent ammonium fluoride residue. Fluorine levels < 0.01 % can be achieved in this way. The moist filter cake is conveyed pneumatically through a system of locks into a fluidized-bed furnace (Fig. 109).

At ca. 500 °C, the uranate is dried, decomposed, and treated with a mixture of hydrogen and steam both to reduce it and to drive out fluorine to < 100 ppm. Furnace charges of some 300 kg are finally heated to 650 °C to reduce the specific surface of the powder to ca. 5 m^2/g.

Thermal Decomposition Processes. Small amounts of uranium dioxide are obtained by thermal decomposition of $UO_2(NO_3)_2$ in a microwave field, yielding a powder with a particularly large specific surface but only moderate sinterability, and by thermal decomposition of sol-gel particles formed by reaction between peptized uranyl nitrate droplets and ammonia.

Dry Process. Another process is the continuous gas- or vapor-phase conversion of uranium hexafluoride with steam and hydrogen. Here, uranium hexafluoride is diluted with nitrogen as an inert carrier gas (to avoid local overheating where the two reactants come in contact); this gas mixture is admitted into a large powder mass (e.g., in a fluidized bed or rotary kiln; see Fig. 110), and the above reaction is carried out in two steps at temperatures below the melting point of UO_2F_2 to avoid inclusions. Large installations in France, United Kingdom, and the United States employ this process. In the fluidized bed method, the primary uranium dioxide particles grow into onionlike shell structures by absorption of UO_2 formed by conversation of UF_6. These product structures were so stable that they could still be detected in polished sections of compacted and sintered pellets. The rotary kiln method uses a gas-phase reaction that produces soft particles whose particle structure disappears in the compaction step.

Figure 110. Rotary furnace for dry $UF_6 \rightarrow UO_2$ conversion
a) UF_6 and N_2 inlet; b) Rotary furnace; c) HF and H_2O condensation

More recently, a modified fluidized bed process was developed and implemented in full-scale production plants in Germany and the United States by Siemens. This process produces soft particles and a free flowing powder.

Quality and Testing. The sintering process for the pellets demands the most well-defined raw materials possible. Along with the processing test, the specific surface area (determined

by the BET method), the dumped and vibrated densities, the oxygen – uranium ratio, and scanning electron micrographs are employed to assess product quality.

Choice of Conversion Process. Dry conversion processes have significant environmental advantages over wet processes. Dry processes recover hydrofluoric acid as a by-product and thereby avoid generation of large quantities of contaminated liquid wastes.

5.3.1.4. Production of Uranium Dioxide Sintered Pellets

Ideally, heat of up to 500 W per centimeter of fuel-rod length must be transferred to the water coolant. At the same time the temperature in the center of the fuel pellet must be as far as possible below the melting point of uranium dioxide (2850 °C). For these reasons, the heat transfer and thermal conductivity of the fuel must be optimized. This applies chiefly to the radial conductivity of uranium dioxide and the heat transfer in the annular clearance between the stack of pellets and the cladding tube. This gap must be closed over the largest possible area in the operating condition. Although the precision of the cylindrical geometry of the cladding tube can be ensured by monitoring the tube rolling process, up to now no industrial sintering process can give a cylinder accurate to ± 10 µm in diameter without a subsequent correction step (grinding).

The pellet shape now used is a cylinder 8 – 10 mm in diameter and 30 – 70 µm smaller in diameter than the cladding tube; the length is ca. 1.2 times the diameter. The pellets deform in reactor service as a result of mainly radial temperature differences; the end faces bulge out and press the edges to the inside of the cladding, which can result in the formation of circumferential grooves. To restrict axial elongation of the fuel stack during operation, one or both end faces of each pellet are dished so that pellets make contact only in the relatively cool outer annular zone. In addition, the cylinder edges are beveled to prevent their pressing against the cladding tube. Edge fractures are thus reduced, and the danger of ceramic fragments breaking off during pellet charging is avoided. These fragments could interfere with the charging operation and create point load inside the cladding tubes, leading to deformation and thus to preferred points of stress-corrosion attack causing pellet cladding interaction (PCI) failures.

Competitive fuel-assembly plants must produce several pellets per second. Therefore, high-speed rotary presses have been developed, which demand a very uniform and free-flowing feed material. If the uranium dioxide powder from conversion is not sufficiently free-flowing, it must be modified by the addition of binders, premolding, crushing and granulation, or screening. To prevent uneven compaction of the powder in the green compact, the wall friction in the mold and the internal friction in the powder must be low. This is accomplished with highly polished hard metal mold surfaces, mold lubrication, and sometimes the addition of a few tenths of a percent of lubricant (zinc stearate) to the powder.

In *sintering*, the stresses induced in molding are transformed to work of compaction (about 18 % shrinkage). This process, which involves recrystallization in the uranium dioxide lattice between 1100 and 1700 °C, is accelerated by oxygen. As oxygen is present in uranium dioxide in a higher than stoichiometric quantity, a sufficient amount of it is available. However, because a stoichiometric final product ($UO_{2.00}$) is required, the last step in sintering is always reduction with hydrogen (or sometimes carbon monoxide). The entire process cannot, however, be entirely separated into two steps, because a completely compacted ceramic is no longer porous enough for the oxygen (which is present mainly as the OH radical under sintering conditions) to diffuse away rapidly.

Sintering furnaces are usually operated with dry or partially water-saturated hydrogen. At 1700 °C, the entire operation (of which sintering proper takes only a few minutes) is complete after 2 – 3 h. Aluminum oxide-lined pusher type or walking-beam furnaces with electrical heating by molybdenum coils are employed because of the high temperature. Energy can be conserved, if sintering is performed in carbon dioxide at 1100 °C and the pellets are subsequently reduced with hydrogen at 1100 °C in a furnace zone separated from the first section by a hot-gas lock. Depending on the pellet size and the quality of the edges, the pellets can pass through the sintering process either loose in molybdenum pans or racked with molybdenum spacer plates.

The cylindrical shape is next brought to the desired diameter by centerless *grinding*. The pellets are washed and dried, and defective pellets are removed. Chemical and physical tests are performed (purity, uranium content, O: U ratio, moisture content, density and dimensions, plus sampling inspection of the microstructure by preparation of polished sections), and in this way only high-quality pellets complying with specifications are incorporated into the fuel rods.

$UO_2 - Gd_2O_3$ Pellets. To allow higher target burnups and smooth the neutron flux in the reactor, the initial excess reactivity of the, in this case, more highly enriched fissile material must be compensated by burnable neutron absorbers. For this purpose, uranium dioxide powder is mixed with up to 10 % gadolinium (III) oxide powder before the pellet fabrication operations described above. Interdiffusion of uranium dioxide and gadolinium (III) oxide usually does not yield a homogeneous mixed crystal; thus restrictions on the microstructure, a somewhat lower thermal conductivity, and an altered pore structure must be accepted. Because confusion and contamination of pure with Gd-doped UO_2 would have grave consequences for local heat transfer, the production lines must be strictly separated. Westinghouse uses a pellet surface coating with boron (ZrB_2) instead of the widely used homogeneous Gd doping of the pellet volume.

5.3.1.5. Production of Fuel Rods and Fuel Assemblies

The cladding tube represents the essential barrier against the escape of fissile materials and fission products into the coolant and, in the other direction, against mechanical and chemical attack on the ceramic fuel by the flowing coolant (water or steam). For light-water reactors, Zircaloy has provided a suitable compromise among mechanical strength, chemical stability, and neutron absorption (see Section 3.1.4.1). It is delivered to the fuel-rod plant as complete cladding tubes with some excess length. The material is annealed above 830 °C, the temperature of the $\beta - \alpha$ phase transition (at which Zircaloy becomes ductile); passed through a final train of pilger rolls to accomplish some 25 % of the hardness gain attainable with cold rolling and subjected to ultrasonic inspection for pores and cracks. In this way, the cladding material going into the reactor has about the same strength that would be produced during operation through the opposing actions of annealing at service temperature and radiation-induced embrittlement (resulting from dislocations in the metal lattice). The tube surface is polished and carefully washed to ensure the required cleanliness needed as well as smoothness of surface which is the basis for a uniform oxide film in the reactor. To achieve higher resistance against waterside corrosion claddings with Zr based materials slightly outside the ASTM specification – partly with the addition of vanadium and/or niobium and binary Zr – Nb alloys – are used increasingly [203]. Siemens introduced duplex cladding with a 20 % highly corrosion resistant outer layer on standard Zircaloy material.

Fuel-Rod Fabrication. The first step in fuel-rod fabrication is to close one end of the cladding tube with a welded plug. The pellets are placed end to end in V channels, forming stacks and are mechanically pushed or vibrationally charged into the cladding tube with the least possible damage and with no edge breakage. A coil spring is inserted to hold the stack of pellets in end-to-end contact during operation, because voids would cause hot spots in the fuel rods. Heat transport in the clearance (annulus) between the cladding tube and the pellets is improved by evacuating the space and filling it with helium. A saving in thickness of the cladding is possible if the system pressure in the PWR (15.5 MPa at operating temperature) is counteracted by prepressurizing the rod to 2.1 – 2.7 MPa (measured cold). Rods that are used for BWRs are prepressurized to about 0.5 MPa. The cladding tube is then closed with a second plug. Either this operation is performed under helium pressure (one-step welding), or an axial hole about 1 mm in diameter is left in the plug and helium is injected later; the hole is then closed by subsequent spot-welding (two-step welding). The two-step welding operation is necessary if the end plug is welded in by the tungsten – inert gas (TIG) method, because it is difficult to weld by this method under helium pressure. Because of this complication, flash butt welding (also called "resistance pressure welding") has been adopted. This technique allows one-step application of

the plug. It offers a very low rate of defects because of the high mechanical pressure in the annular melt zone, which prevents pore formation and results in a narrower fused zone of altered microstructure.

Figure 111. PWR fuel assembly (Siemens photo)

Helium leak testing, which can detect leaks down to $10^{-11}\,\mathrm{bar\,L^{-1}\,s^{-1}}$, is also common. The test involves an evacuated chamber and a mass spectrometer. The final rod check is performed in a rod scanner, where the correct pellet enrichment and axial location is determined.

Fabrication of Fuel Assemblies. The fuel assembly (Figs. 111 and 112) initially consists of a prefabricated skeleton of spacer rods (and control rod guide tubes in the case of PWR assemblies) holding the spacer grids or assemblies. The fuel rods are inserted in layers into these spring-clip grid assemblies; a PWR assembly has up to 300 fuel rods and a BWR assembly up to 100 rods. In a PWR assembly no fuel rods are connected to the upper and lower tie plate, only the guide tubes. Traditionally, in BWR assemblies a few tie fuel rods are connected to both end pieces. However, modern 10×10 designs by Siemens and ABB avoid the high operating loads on these fuel rods by applying a skeleton or a subassembly structure.

Figure 112. BWR fuel assembly (Siemens photo)

The final operation is a careful dimensional check with vertical fuel assembly (not horizontal because the rods bend under their own weight).

5.3.2. Fuel Elements for High-Temperature Reactors

5.3.2.1. General Aspects

The main characteristic of the HTR is its ability to make the energy generated by nuclear fission available at a high temperature. Coolant outlet temperatures of 750 – 950 °C necessitate fuel-element surface temperatures higher than 1000 °C. These conditions almost inevitably lead to the use of helium as coolant and to a fuel element made exclusively of ceramic materials.

The fuel elements currently used in the high-temperature reactor differ greatly in shape. The HTR fuel element developed in the United States [204], [205] and in Japan [206] is a large, hexagonal prism. Germany [207–209] and the former Soviet Union [210–212] use a spherical fuel element. Despite these very different shapes, the elements all have the same basic design. The fuel they contain is in the form of microspheres,

each the size of the head of a pin, coated with several layers of ceramic material. These coated particles are embedded in a graphite matrix. The graphite serves simultaneously as structural and a moderator material.

From the very beginning, development of the high-temperature reactor was closely linked with the uranium – thorium fuel cycle [213–215]. Highly enriched uranium (HEU) with ca. 93 % enrichment is used as fuel for the fuel cycle and thorium is added as fertile material. Neutron capture leads to the conversion of thorium into the fissile isotope uranium-233 with protactinium as the intermediate:

$$^{232}\mathrm{Th} + \mathrm{n} \longrightarrow {}^{233}\mathrm{Th} \xrightarrow{\beta^-} {}^{233}\mathrm{Pa} \xrightarrow{\beta^-} {}^{233}\mathrm{U}$$

Compared to the uranium – plutonium cycle, the HEU cycle is clearly of economic advantage to the HTR. Moreover, with this fuel cycle, large thorium deposits can be used for energy production by nuclear fission. Both prototype plants – Fort St. Vrain (330 MW) in the USA and the THTR (300 MW) in Germany – were operated by using the HEU fuel cycle.

Fuel kernels of the THTR elements contain thorium and highly enriched uranium as a mixed oxide in the ratio 10 : 1. The diameter of these very dense sintered kernels is 400 µm. In the fuel elements of the Fort St. Vrain reactor, the fuel kernels consist of the mixed carbide $(U, Th)C_2$ having a thorium: uranium ratio of 4.25 : 1. The diameter is in the range of 100 to 275 µm. Apart from these fuel kernels, others kernels contain fertile material only in the form of ThC_2 and have a diameter of 300 – 500 µm.

In view of the nonproliferation of materials employed in nuclear weapons, the trend worldwide in the HTR line at the beginning of the 1980s moved toward the uranium – plutonium cycle, [i.e., the fuel cycle with lightly enriched uranium (LEU)] and away from highly enriched uranium [216], [217]. Fuel concepts in Germany, the former Soviet Union, and Japan provide for the use of uranium dioxide fuel kernels with 6 – 10 % uranium enrichment. The diameter of the kernels is 500 µm (Germany, Former Soviet Union) and 600 µm (Japan). The use of thorium as fertile material is still being pursued in the United States. This fuel concept provides for the application of uranium oxide carbide (UC_xO_y) fissile kernels. The uranium has almost a 20 % degree of enrichment, and the kernels have a diameter of 300 µm, whereas the diameter of the kernels of fertile material is 500 µm.

Coated Particles. As with all other reactor concepts, fission products in the HTR should be retained in the fuel element as much as possible and should not enter the coolant cycle. The graphite in which the fuel particles are embedded cannot retain the fission products because of its porosity. This task is carried out by a system of layers, covering each individual fuel kernel [218], [219]. When the HTR fuel element was first developed, this layer system consisted of two pyrolytically deposited carbon layers (BISO coating). However, an additional layer of silicon carbide (TRISO coating) was found not only to markedly increase the mechanical stability of the coating system, but also to improve considerably the retention capability for solid fission products that tend to diffuse at these temperatures. Although the fuel particle of the THTR fuel element still has a BISO coating, all currently used fuel element concepts worldwide provide for a TRISO coating [220]. Therefore, the most highly developed and tested fuel particle with this coating is described here, namely, the particle for the LEU fuel element of the German THTR successor plants.

The innermost layer, the *buffer layer*, consists of very porous pyrocarbon ($\varrho = 1.0$ g/cm^3) and has a thickness of 95 µm. The functions of this layer are:

1) To buffer the swelling of the fuel kernel under irradiation (i.e., to prevent the resulting mechanical strain on the subsequent layers);
2) To attenuate fission products that leave the fuel kernel and originate from fissions near the surface (recoil atoms), thereby preventing damage to subsequent layers;
3) To provide void volume for gaseous fission products and thus prevent a dramatic pressure increase in the particle.

The layer above the buffer layer is made of dense pyrocarbon ($\varrho = 1.9$ g/cm^3) with a thickness of 35 µm. This gastight pyrocarbon layer protects the next very important silicon carbide layer from corrosive attack by fission products. Moreover, this layer prevents the penetration of hydrogen chloride and other chlorine – containing compounds into the buffer layer. These compounds are formed on deposition of the sili-

con carbide layer (see Section 5.3.2.2) and contribute to the corrosion of this layer during reactor operation.

The silicon carbide layer is 35 µm thick and practically reaches the theoretical density of silicon carbide ($\varrho = 3.2\ g/cm^3$). This layer acts, above all, as a diffusion barrier for solid fission products. In addition, it gives the particle a higher mechanical strength. This is especially important because the particle and its coating constitute a pressure vessel that must withstand inner pressures of up to 20 MPa.

The outermost layer is made of pyrocarbon ($\varrho = 1.9\ g/cm^3$) and is 40 µm thick. It protects the brittle silicon carbide layer to a certain extent, contributes somewhat to the stability of the pressure vessel, and acts as a barrier for gaseous fission products if the silicon carbide layer fails.

Fuel Elements. The *spherical fuel element* developed in Germany (see Fig. 113) has a diameter of 60 mm. The actual fuel zone containing the coated particles has a diameter of 50 mm. The surrounding fuel-free shell is 5 mm thick. Both the fuel zone and the fuel-free shell consist of the same type of graphite, which, in contrast to normal graphite, still contains a certain proportion of nongraphitic carbon due to the manufacturing process [221], [222].

Figure 113. Spherical fuel element (Germany)
a) Matrix; b) Fuel-free shell; c) Fueled zone; d) Kernel; e) Buffer layer; f) Inner pyrocarbon layer; g) Sic layer; h) Outer pyrocarbon layer

The spherical fuel element developed in the former Soviet Union also has a diameter of 60 mm. The diameter of the fueled zone, however, has not yet been stipulated definitely. Diameters of 40 and 50 mm are currently being considered.

The *block-shaped HTR fuel element* developed in the United States (see Fig. 114) is a hexagonal prism made of graphite having a width over flats of 359.1 mm and a height of 793 mm. It is provided with axial holes to receive the fuel rods and to guide the coolant gas. The fuel rods have a diameter of 15.9 mm and a length of ca. 60 mm. They consist of a relatively porous graphite matrix in which the fissile and fertile coated particles are embedded.

The *Japanese fuel element* concept (see Fig. 115) also provides for block-shaped, hexagonal fuel elements with a width over flats of 360 mm and a height of 580 mm. The fuel compacts containing coated particles have the form of hollow cylinders. They are put into graphite tubes, that are, in turn, inserted into corresponding holes in the graphite block. Coolant gas flows through the gap between the graphite block and the graphite tube.

5.3.2.2. Production

Production of Fuel Kernels. The production of the spherical fuel kernels can be carried out by powder agglomeration or by wet chemical processes based on solidification of droplets [223], [224]. A narrow bandwidth of the kernel diameter and an almost ideal spherical shape are essential for good irradiation performance of the coated particles. These quality requirements can be met more easily with wet chemical processes that dry methods are no longer of interest. Many variations of the *wet chemical* process have been developed. However, the gel precipitation process and the hydrolysis process (H process) are practically the only processes of technical importance today.

Gel Precipitation. In the production of *uranium dioxide kernels* by gel precipitation (Fig. 116), a uranyl nitrate solution is the starting material [207], [208]. This solution is preneutralized to a certain degree with aqueous ammonia before the addition of organic additives [poly(vinyl alcohol) and tetrahydrofurfuryl alcohol]. Forming is achieved by the vibrodropping of this feed solution. The droplets are subjected to a lateral stream of gaseous ammonia as they fall. This results in presolidification based

on the fact that ammonia-containing uranium trioxide hydrate is formed, which covers the droplet like an elastic skin. The drop is now so stable that it no longer loses its round form when it hits the surface of the precipitation bath.

Figure 116. Fuel kernel fabrication

The reaction of uranyl nitrate with ammonia is brought to an end in the precipitation bath, an aqueous solution of ammonia. Small, translucent, gellike kernels are obtained. After aging, the kernels are washed first with water and then with alcohol. The ammonium nitrate formed in the kernels is dissolved in this process. Subsequently, the required process steps at higher temperature can be performed: drying and calcining in air, reduction, and sintering in an atmosphere of hydrogen. The kernels are then sieved, and the small number of highly unround kernels are separated by using a vibration plate inclined against the horizontal (classifying).

The use of the gel precipitation process for the production of kernels of *mixed oxides of uranium and thorium* requires a starting feed solution that contains uranyl nitrate, thorium nitrate, and poly(vinyl alcohol). Tetrahydrofurfuryl alcohol is not required and the steps – preneutralization, aging, and reduction – in the flow diagram are not necessary because of the different chemical behavior of uranium and thorium.

If appropriately modified, this process is also suitable for the production of *carbide and oxide – carbide kernels*. The amount of carbon required for the formation of carbide in each case is added to the feed solution as carbon black. Both carbide formation and sintering are carried out between 1400 and 1800 °C in argon. If uranium carbide kernels are required with a density > 90 % of the theoretical density, further treatment at about 2500 °C (melting) is essential. Here, too, the last two steps of fabrication are sieving and classifying. The gel precipitation process is used in Germany to produce the predominant part of AVR fuel and all fuel kernels for THTR fuel elements.

Hydrolysis Process. In the gel precipitation process, the ammonia that causes gelation is brought in contact with the droplets of feed solution from the outside (external gelation). In the H process, however, the ammonia is produced inside the droplets of feed solution by the chemical decomposition of hexamethylenetetramine, which serves as the ammonia carrier (internal gelation) [225–228]. As a result, the H process can also be used to make uranium dioxide kernels with a diameter of 1 mm or more, which cannot be achieved with the gel precipitation process.

The aqueous feed solution in the H process normally contains uranyl nitrate in relatively high concentrations, urea (to stabilize the solution by complex formation), and hexamethylenetetramine. This feed solution must be kept at < 5 °C because higher temperature initiates the decomposition of hexamethylenetetramine into ammonia and formaldehyde, resulting in early precipitation of the uranium compound.

The cooled feed solution is dripped into a hot precipitation bath of tetrachloroethylene. The ammonia liberated at the high temperature initiates a hydrolysis reaction and thus causes the solidification of the droplets in the precipitation bath. A short temperature treatment then

frees the kernels from the still adhering, freely volatile tetrachloroethylene. The ammonium nitrate formed and the remaining organic substances are removed from the kernels by subsequent washing with ammonia-containing water. After the kernels have been dried in air, they are reduced (at ca. 500 °C) and then sintered (at ca. 1500 °C) in a hydrogen atmosphere.

Coating. Coating of the kernels is carried out by chemical vapor deposition (CVD) of pyrocarbon or silicon carbide from the gas phase in fluidized beds [229]. The core of the fluidized-bed installation is a gastight, water-cooled, cylindrical steel vessel with a built-in graphite tube as heating conductor [207], [230]. This conductor surrounds another graphite tube, the working tube, which has a conical base provided with inlet nozzles through which the coating gases and the carrier gas flow into the reaction chamber. The coating gases are pyrolytically decomposed at the temperatures prevalent here, resulting in the deposition of pyrocarbon and silicon carbide on the fluidized fuel kernels in the reaction chamber. The desired density and structure of the layers can be adjusted by the appropriate choice of process parameters such as temperature, coating gas concentration, and gas flow. The thickness of the layer is then a function of time. Coating is usually carried out in batches of 4 – 10 kg of fuel kernels.

The *buffer layer* of the TRISO coating is deposited by the decomposition of acetylene at about 1200 °C. The starting material for the two *dense pyrocarbon layers* is a mixture of acetylene and propene. The optimal decomposition temperature of this mixture is ca. 1300 °C. The *SiC layer* is deposited from methyl trichlorosilane at ca. 1500 °C.

The coated particles are removed from the fluidized bed and sieved. Nonspherical particles, which have a lower mechanical stability as a result of their shape, are separated with the help of vibration plates [208].

As far as irradiation properties are concerned, the important characteristics of quality are a minimum variation in layer thickness and layer density and, above all, as small an amount as possible of coated particles with a production-related, defective silicon carbide layer. With particles of good quality, the fraction of defect SiC-layers today is less than 10×10^{-6} ; i.e., less than 10 out of 10^6 particles have a defective silicon carbide layer.

Fabrication of Fuel Elements.

Spherical Fuel Elements. In Germany, the fabrication of spherical HTR fuel elements (Fig. 117) begins with coated fuel particles and binder-containing graphite powder, also called " molding powder" [207], [231]. This is prepared by kneading a graphite powder mixture with a solution of the binder (phenolic resin) in methanol, and by subsequently drying and grinding the kneaded material. In an overcoating process, the coated particles are provided with a layer of molding powder of approximately 200-µm thickness. This overcoating layer functions as a spacer, preventing direct point contact between the particles during pressing of the elements and, consequently, resulting breakage of particles. To guarantee the required overcoating quality, these particles are sieved and sorted on a vibration plate, as described for coated particles.

By starting with the overcoated particles and the molding powder, the fueled zone is first premolded and then, in a second step, a fuel-free shell of molding powder is shaped around the fueled zone. In view of the high anisotropy of graphite, both molding steps are carried out in silicone rubber molds. Hence, an approximately isostatic pressure distribution is achieved on pressing and, consequently, sufficiently good isotropy in the element.

The spheres attain their exact shape by mechanical processing (lathing). They are subsequently heated first to 800 °C in the absence of oxygen to carbonize the binder and then to 1950 °C in vacuum for gas removal and purification. Until now, this process has been used in Germany to produce approximately 1.2×10^6 fuel elements for application in AVR and THTR plants.

In the former Soviet Union, the production of spherical fuel elements is still in the developmental stage. One of the methods being investigated is the molding of binder-containing graphite powder and coated particles in steel molds at elevated temperature [232]. The binder used is coal tar pitch. In another production process, the use of a graphite matrix bound with pyrocarbon is being tested. Here, spherical compacts of relatively low density are produced by the molding of graphite powder and coated par-

Figure 117. Fabrication of the spherical fuel element (Germany)

ticles in steel molds [233]. The insertion of pyrocarbon, which acts as binder, is achieved by the very slow pyrolytic decomposition of natural gas in the pores of the compacts (impregnation from the gas phase).

Prismatic Fuel Elements. Prismatic fuel elements, such as the elements produced in the United States for use in the Fort St. Vrain reactor, consist essentially of prefabricated electrographite blocks provided with axial holes and cylindrical fuel rods [234]. In the production of these fuel rods, dosing of the number of particles of fuel and fertile material required for each fuel rod is carried out first. After homogenization, the particle mixture is transferred to a steel mold and heated to approximately 170 °C. A heated, plastic matrix of graphite powder and pitch binder is then injected into this preheated particle bed, which has been fixed in shape in the mold. The "green" fuel rods are extruded after the mold is cooled. They are then packed into a bed of aluminum oxide powder and heated in inert gas to about 800 °C to carbonize the pitch binder. The low inherent stability of the green fuel rods in the heating phase necessitates this measure. The carbonized fuel rods are subsequently subjected to gas purification with hydrogen chloride at approximately 1700 °C and then to annealing in inert gas at about 1800 °C. Treatment with hydrogen chloride results not only in the removal of impurities from the graphite matrix but, more important in removal from the fuel rods of uranium and thorium released by particle breakage. The fuel rods are inserted into the corresponding holes in the graphite block, which are then sealed with graphite plugs.

Although the elements contain the same number of fuel rods, they must have different amounts of uranium and thorium, depending on their position in the reactor core. For this reason, two types of particles of fissile and fertile material containing different concentrations of heavy metal in each case – achieved by using the same layer thickness for different kernel thicknesses – are employed in the production of fuel elements for the Fort St. Vrain reactor (i.e., in

total four different types of particles). The different heavy-metal concentrations required in the fuel element were adjusted by suitable mixing of different types of particles. In the future, however, only one type of fissile and one type of fertile particles in a suitable combination with graphite particles for volume compensation will be used. This will greatly simplify the process.

The production of fuel elements for the *Japanese HTR*, presently in the planning stage, has only one exceptional feature, the fuel compacts [235]. The graphite blocks and graphite tubes are delivered prefabricated. The production and coating of uranium dioxide kernels with an average uranium enrichment of 6 % proceeds according to the processes described above.

As with the spherical THTR fuel element, production of the fuel compacts starts with coated particles and resinated graphite powder. In contrast to the production of spheres, the entire amount of resinated graphite required for a certain number of particles is granulated onto this number of particles. The overcoated particles are then molded into appropriate steel molds, at a temperature above the softening point of phenolic resin to the fuel compacts. The compacts are then carbonized and annealed as described for the fabrication of spherical elements. Fuel element assembly occurs in a subsequent step.

5.3.3. Fuel Assemblies made from Reprocessed Plutonium

5.3.3.1. Availability of Plutonium [236]

In the neutron field of the LWR, ^{239}Pu is formed from ^{238}U (by neutron capture and two β decays) and at the same time fissioned with the evolution of heat. At equilibrium between generation and fission, toward the end of burnup, plutonium contributes nearly 40 % of fission-produced heat. In the burnup range of interest, between 30 and 60 MW · d/kg fuel, the discharged fuel contains slightly less than 1 wt % plutonium, and with increasing burnup the isotopic composition of this element is shifted increasingly toward the even-numbered isotopes 238, 240, and 242 (which are barely fissile by thermal neutrons) until, eventually, only a little more than 60 % of the plutonium discharged remains fissile by thermal neutrons (i.e., the isotopes 239 and 241). Weapons grade plutonium, which is produced from very lightly irradiated fuel (less than 0.4 MW · d/kg), has very high concentrations of ^{239}Pu (93 – 95 %). Therefore, the use of light water power reactors for production of weapons grade plutonium is the most uneconomic way due to the inherent batch reload scheme of light-water reactors and has never been employed by the existing and suspected nuclear weapons states.

At present, the global total quantity of plutonium, in all forms, is about 1240 t (Table 56). Of this total, approximately two-thirds is contained in stored spent fuel from civil power reactors. The OECD Nuclear Energy Agency (NEA) estimates that 50 t of plutonium are generated worldwide in the 427 operating reactors (as of January 1998) every year. In 1995 the amount of "civil" plutonium (from reprocessed power reactor fuel) in the separated form, kept in stores, was 140 t. Two industrial factors currently control the transformation of separated plutonium in reactors: MOX fuel fabrication capacity and the number of reactors licensed to use MOX fuel. These parameters will control supply and demand for MOX in the coming years. Since the current capacity of MOX fuel fabrication plants for thermal reactors is limited, the world inventory of separated plutonium continues to increase. In 1995 the stock of separated plutonium increased by some 14 t (22 t were separated by reprocessing, 8 t of which were used as MOX in LWRs and fast reactor development programs).

Table 56. Present and predicted stocks of plutonium globally (in t) [237]

Civil plutonium	1995	2010
In spent reactor fuel	800	1400
Separated and stored plutonium	140	150
In fast reactor fuel cycle	30	550
In thermal MOX fuel cycle	20	
Subtotal	990	2100
Military plutonium	249	not available
Total	1239	

In addition worldwide, some 250 t of military plutonium are held, about a fifth of the total plutonium inventory. The largest quantity, nearly 150 t, is kept in Russia. Most of the remainder

is in the USA (about 100 t) with United Kingdom, France, and China probably holding less than 10 t each [238]. Following agreements between the USA and Russia to dismantle surplus nuclear weapons, the USA has declared 52.5 t of weapons grade plutonium as no longer required for defense purposes. Russia has also declared that it has a similar excess but not yet stated a precise quantity. The United Kingdom, France and China have not declared an excess of plutonium over their military requirements. Reduction of the quantity of surplus weapons plutonium is generally viewed as a higher priority than plutonium reduction of produced by reprocessing from civil nuclear power generation because of the former's greater potential as a security risk. Two main options for the management of surplus military plutonium are considered at present: (1.) Consumption as MOX fuel in reactors in a once-through fuel cycle, which renders surplus weapons plutonium into spent fuel and leads to the degradation of the plutonium's isotopic quality to a nonweapons grade level. (2.) Immobilization (e.g., by vitrification) and disposal in a final repository, this option is required for existing surplus plutonium which is unsuitable for use in MOX fuel because of, e.g., chemical contamination.

5.3.3.2. Utilization Strategies

From the reactor engineering standpoint, ^{235}U and ^{239}Pu (the most important fissile isotope of Pu) differ somewhat. At higher neutron energies plutonium has a favorable ratio of fission to capture cross-sections so that, in the presence of ^{238}U, more plutonium can be generated from this nuclide than is consumed in fission reactions. This breeding process takes place in the breeder reactors with fast neutrons (see Chap. 4). Currently, fuel assemblies of most fast breeder reactors consist of stacked pellets of a mixed UO_2–PuO_2 ceramic containing up to 28 % fissile plutonium and enclosed in steel cladding tubes.

5.3.3.3. Requirement for Mixed-Oxide Thermal Fuel Assemblies

As long as the demand for plutonium breeder fuel assemblies remains lower than the rate of plutonium production, it is desirable to reduce the excess by recycling it to existing LWRs. The recycled mixture of plutonium isotopes has a fission cross-section > 30 % greater than that of ^{235}U, so neutron physics would be optimized by distributing this fissile material as evenly as possible in the reactor to prevent local overheating. However, homogeneous mixing with the total uranium dioxide in all the pellets throughout the entire reactor, is uneconomical because the high radiotoxicity of plutonium would increase processing costs and complexity. Mixed-oxide fuel assemblies are therefore employed. In each row of fuel rods in such an assembly, the plutonium content increases from outside to inside. As many as six different contents of fissile Pu (range 0.4 – 1.7 of average) are used in boiling-water reactors; three (0.5 – 1.2 of average), in pressurized-water reactors [239]. To flatten neutron-flux peaks when fissile contents are increased for higher burnups, hollow or water-filled rods and/or individual UO_2 – Gd_2O_3 rods are included in the fuel assembly. Since the assemblies are repositioned in the reactor several times over their service lives to obtain uniform burnup, MOX assemblies must also be interchangeable with UO_2 assemblies, so that the two kinds have the same geometry and are subject to the same limits on thermal and mechanical loads. Mixed reactor core designs with up to 30 – 50 % MOX fuel assemblies have been licensed [240], [241]. Also full MOX cores are feasible. The corresponding assembly design for PWRs is even simpler than that of mixed cores. For full MOX cores a lower content of fissile plutonium in the peripheral fuel rods is not required which is necessary in mixed cores to accommodate for the spectral shift between MOX and UO_2 fuel assemblies (a "harder", i.e., less moderated neutron spectrum exists in MOX assemblies). MOX manufacturing plants as well as transportation and reactor operations with MOX fuel have to – and can – meet the same safety and environmental standards as applied in the UO_2 fuel cycle. The same amount of electricity can be generated from a MOX fuel assembly as from a substituted UO_2 assembly, provided they are operated to the same burnup.

5.3.3.4. Requirement for Fast Breeder Fuel Assemblies

Since the fuel for a fast breeder consists solely of a mixture of uranium and plutonium, the chemical form and geometry of fuel rod and assembly can in principle be chosen freely, in contrast to the recycled fuel for a thermal reactor which must match the enriched UO_2 fuel. The constraints are that (1) the fuel must be chemically compatible with the sodium coolant and steel cladding at the operating temperature, and (2) the fuel must withstand the high neutron fluences (up to 10^{23} neutrons/cm^3 over the fuel-assembly service life) without massive amounts of strain energy. Deformation due to power excursions has to remain controllable.

Therefore, mixed-oxide fuel pins with austenitic steel cladding have been developed (wall thickness ca. 0.4 mm); the fuel pellets are between 6 and 7.5 mm in diameter. The highest central temperature in the pins (800 – 1000 °C) is far below the melting point of the mixed oxide (2500 °C). The stack of pellets displays inherent self-regulation in power excursions (decrease in reactivity because of axial expansion combined with Doppler broadening of resonance peaks when the temperature rises, see Section 1.3.6); and these facts make the system relatively stable. Ample experience in working with fissile oxides means that processing difficulties need not be feared. However, the drawback – the relatively low thermal conductivity of the oxides – dictates a small pin diameter (6 – 8 mm). Another disadvantage is that conversion of tetravalent fissile materials to mono-, di-, or trivalent fission products leads to more than the stoichiometric quantity of oxygen in the fuel matrix as burnup increases (i.e., the presence of free oxygen). Free oxygen, in combination with fission-product iodine and cesium, can lead to corrosion of the cladding tubes from inside, in addition cesium forms chromates with the cladding tube material. As a result, it has become necessary to fabricate the oxides somewhat substoichiometricly.

In contrast, not only do alternative fuels, such as monocarbides, mononitrides, or carbonitrides of uranium and plutonium, have a threefold better thermal conductivity than the oxides, but also their higher density permits a higher breeding ratio with a given neutron flux. However, advanced methods are required for production and reprocessing of these fuels. Tests on carbide fuel assemblies have been carried out in only a few of the operating breeders. Only one small reactor (BR-5, former Soviet Union) had a complete carbide fuel inventory.

Table 57. Radiation protection

Protection against	Protective measures
Intake of, or contamination by Pu	α-tight enclosure (glove box, welded plastic bags), pressure difference by forced ventilation
Low-energy γ radiation from Pu (low intensity)	lead shielding in glove boxes
Low-energy γ radiation from daughter nuclides, e.g., ^{241}Am (high intensity)	separation of ^{241}Am from Pu before processing of Pu, lead shielding
	use of hot- cell technology (difficulties were encountered during tests in one case)
	use of mechanization or automation to cut down on manual operations
Neutrons from spontaneous fission (mainly ^{249}Pu and α, n reactions)	water walls or plastic shielding with added absorbers (B, Cd)
	automation
Nuclear excursions (criticality)	limitation on quantities with allowance for moderating ratio and density
	"safe geometry" design of plant
	use of B, Cd, Hf as neutron absorbers (poisons)
Environmental effects	design of buildings and facilities in compliance with guidelines of the Reactor Safety Committee (Reaktorsicherheitskommission)
Third-party action or misuse	surveillance and accountability of nuclear materials

5.3.3.5. Problems in Handling Plutonium

Both the fissiability and the high specific α activity of the odd-numbered plutonium isotopes make this element difficult to work with (see Table 57) [242]. Plutonium recovered in LWR fuel-assembly reprocessing has a specific α activity of 5 – 25 GBq/g and minimum critical masses of ca. 13 kg in dry spherical geometry or ca. 600 g when optimally moderated in water. The specific α activity means that plutonium is highly radiotoxic; its chemical toxicity as a heavy metal is not nearly as important. For persons occupationally exposed to plutonium the limit of intake of plutonium oxide powder based on a current metabolic model is only 400 Bq/a in the lung. Dust inhalation is the most important intake route because the range of the inhaled α

particles is sufficient to reach the lung tissue. This limit is reached if only one dust particle weighing 0.04 μg is inhaled. The atmosphere of the area in which plutonium is handled must therefore be reliably isolated from the worker's breathing air. Alpha-tight enclosure is accomplished if gastight gloveboxes are used. In newer processing plants, manual work is reduced as much as possible through automation, i.e., production is carried out automatically, repair and maintenance manually. Plutonium areas are further shielded – by walls containing lead and moderators (water, plastics) – against γ radiation (from daughter products of ^{236}Pu and ^{241}Pu) and neutrons [from even-numbered plutonium isotopes, chiefly ^{240}Pu, and from (α, n) reactions with $^{17}O_2$ and $^{18}O_2$].

So that critical configurations can be totally avoided during processing, moderators are excluded wherever possible [this means that aqueous solutions of plutonium salts can only be processed if the surface – volume ratio is large enough to guarantee sufficient neutron leakage ("geometrically safe equipment")], and the quantities handled in one place are limited to less than half the critical mass. In many cases, neutron absorbers (boron, hafnium, gadolinium, cadmium) are also employed.

Many obstacles exist to the misuse of plutonium from irradiated LWR fuel for weapons purposes to avoid liberation of its potential explosive force. Most important in this respect is the chance of preignition due to neutron-emitting higher isotopes, requiring a highly sophisticated ignition technology. Even then the explosive yield is principally unpredictable. However, reactor plutonium cannot principally be excluded as raw material for weapons. These facts have led to the most stringent security measures to guard against the diversion or misuse of this material. National and international inspectorates monitor the flow of fissile materials. Access to these materials is under strict surveillance. Sensitive monitors prevent undetected removal from the controlled area.

5.3.3.6. Fabrication of Mixed-Oxide Fuel Assemblies

Aside from experimental quantities of metal and carbide fast breeder fuel, the processing of plutonium into fuel assemblies today resembles uranium dioxide technology (see Section 5.3.1.5). Earlier, several attempts were made to introduce simpler techniques (which would better lend themselves to automation and remote control), in place of the classical ceramic operations with many individual steps, which require the handling of fine powders; high geometrical precision in molding, sintering, and grinding; and thus large amounts of manual work. None of these experiments, however, was successful enough for the developers to undertake the costly process of gaining approval for widespread power-reactor use.

Modifications of UO_2 Process for MOX Fuel Assemblies. An important point with regard to fuel use is that 200 times as many fissions per unit time occur in a plutonium dioxide particle as in an adjacent particle of natural uranium dioxide. For this and a number of other reasons (Doppler broadening, self-shielding), the plutonium dioxide must be distributed as finely and uniformly as possible in the uranium dioxide matrix. On the other hand, because the surface of a ceramic in normal air is always coated with adsorbed water, the flowability of powders declines as grain size decreases and the tendency to self-agglomeration increases. Thus, it becomes more difficult to charge the powder into molds, and problems in industrial pellet fabrication are created. Therefore, fine plutonium dioxide powder (mean grain size 1 – 2 μm; e.g., produced by calcination of precipitated plutonium oxalate) was mixed carefully with flowable uranium dioxide (agglomerate size 20 – 40 μm; product from AUC process) in such a way that the fine plutonium dioxide coated the uranium dioxide grains, and the still-flowable powder was subsequently molded. This method was technologically simple and successful. However, this approach had to be abandoned when it was discovered that interdiffusion of uranium dioxide and plutonium dioxide (both in sintering and during later in-pile irradiation) was insufficient for the formation of homogeneous (U,Pu) O_2 mixed crystals. Therefore in reprocessing, up to 15 % of the plutonium dioxide remained in the dissolver sludge, in acid-insoluble form, when the fuel was dissolved in nitric acid. In response to this finding, the fuel assembly, even before irradiation, was required to contain plutonium in HNO_3-soluble

form (i.e., as a homogeneous mixed crystal with less than 40 % Pu). This standard is met in a variety of ways today. With plutonium nitrate as starting product, a mixture of $Pu(NO_3)_4$ and $UO_2(NO_3)_2$ solutions with a maximum plutonium content of 40 % is prepared. The process developed by the Power Reactor and Nuclear Corporation (PNC) in Japan converts this mixture to the oxides by (1) evaporating the solution in a microwave field, (2) calcining the salts, (3) reducing the agglomerate size by milling and sieving, and (4) reducing to the dioxides with hydrogen. A process tested at Risley (BNFL, UK) starts with stabilized mixed nitrate solutions, generates droplets, and solidifies these to sol-gel spheres in gaseous ammonia. The particles are calcined to obtain a moldable charge of spherical homogeneous mixed crystals. Siemens developed the *A(UPu)C process*, a modified AUC process (see Section 5.3.1.3). Here, a mixed solution of the uranium (VI) and plutonium (VI) nitrates, is used to yield $(NH_4)_4[(U, Pu)O_2](CO_3)_3$ as an intermediate; this product is calcined to give homogeneous $(U, Pu)O_2$. This "A (U, Pu)C" process, like the microwave technique, has been tested on several hundred kilograms of plutonium; it yields a powder that requires no further treatment before being mixed with UO_2 (from the AUC process) and molded.

The *Cogema reprocessing plant*, however, produces PuO_2 from the oxalate, and the product must be converted into a completely acid-soluble MOX fuel [243]. Two very similar processes have been developed for this purpose: Mimas at Belgonucleaire (and later improved at Cogema) and OCOM at Siemens. Each is based on the intensive milling and mixing of part of the UO_2 with PuO_2. In the Mimas process, UO_2 agglomerates from very small (1 – 5 μm) primary particles (from the CEA dry conversion plant at Cadarache), with a tendency toward self-agglomeration, or UO_2 from AUC processes are mixed with the PuO_2 and ground for about 24 h in a large tubular ball mill. The powder is then put through a self-agglomeration process after removal of grinding balls, mixed with more UO_2 from the same source, and molded into pellets. In the OCOM process, PuO_2 and UO_2 (from the AUC process) are the feeds. A few tenths of a percent of a grinding aid is added to prevent self-agglomeration, the mixture is ground for 12 h to achieve a very high solubility, and the resulting powder is mixed with more AUC-product uranium dioxide and molded.

The added plutonium modifies the properties of the ceramics because plutonium dioxide, in contrast to uranium dioxide, can form a stable sesquioxide Pu_2O_3 under the reducing conditions in the sintering furnace (the atmosphere contains at least ten times more hydrogen than water). As a result, the product uranium dioxide is slightly substoichiometric. The Pu_2O_3, if present in isolated grains in the sinter, is an interfering species not just because its crystal lattice is different (hexagonal instead of face-centered cubic), but also because it can incorporate hydrogen (formed by the radiolysis of adsorbed water) into interstitial lattice sites in a particularly stable way [244]. To prevent local hydride damage (sunburst defects) on the inside of the Zircaloy cladding, the content of $(H_2 + H_2O)$ in the ceramic matrix should be held below 10 ppm determined as H_2O. This requires that the pore shape, pore size, and residual moisture content in the ceramic be carefully matched. If a large fraction of fission products must be accomodated by the fuel, a fast breeder fuel is required that contains a certain amount of pores of a distinct shape and size, i.e., its density is outside the common density range for sintering (92 – 96 % of theoretical). In this case pore-forming agents such as ammonium uranyl carbonate, zinc stearate, or oxamide are added.

Another feature of MOX fabrication is that the hydrogen used in sintering is diluted with inert gases (N_2, Ar) to below the explosion limit (< 8 %) for safety reasons. Particular care is needed so that traces of plutonium will not be deposited on the outside of the cladding tube when the pellets are charged into it. Only in this way can the welded fuel rods be handled like uranium dioxide rods.

Testing and Analysis. Mixed-oxide fuel rods also undergo several special inspections. In addition to the absence of washable contamination, a uniform plutonium – uranium distribution must be verified, and a γ-spectrometer scan must be performed to make sure that all pellets in a rod belong to a certain production batch.

Assembling. The techniques used for making fuel assemblies from uranium fuel rods can be applied directly. Since a PWR assembly with 500 kg of fuel contains up to 25 kg of plutonium,

the longer-lasting operations must be carried out behind neutron shielding, which usually consists of stacks of borate glass and plastic slabs.

5.3.3.7. Radiation Protection and Safety Aspects

In addition to the legislation and regulations that govern environmental protection and accident prevention in conventional plants, a large number of further regulations and directives apply to the design of a plant for plutonium fuel assemblies. These ultimately bear on the problems listed in Table 57.

5.4. Chemical Reprocessing of Nuclear Fuels

Introduction. The scope of Section 5.4 is the industrial reprocessing of commercial power reactor fuels. The discussion will concentrate on the treatment of fuel elements from light-water reactors because at present these form the most widely used class of commercial nuclear reactors worldwide. A short outlook to the requirements of fast breeder reactor fuel recycle will also be given because if nuclear energy is to become a long-term energy source, the development of FBR systems to industrial maturity will be inevitably required (Section 5.1). In both reactor types, oxide fuels are exclusively (LWR) or preferably (FBR) being used, i.e., slightly enriched uranium dioxide in the LWR, and uranium – plutonium mixed oxide (MOX) in both the LWR and the FBR. As a consequence, this chapter will deal particularly with oxide fuel reprocessing.

History. For a better understanding of the evolution of current reprocessing technology, a short historical review is given [245–248]. Chemical processing techniques for neutron-irradiated uranium fuels were first developed with the aim of producing plutonium for weapons applications. The "production" reactors used as irradiation sources had in common the utilization of uranium metal fuels. These were only slightly irradiated to burnup levels of a few hundred MW · d/t, to obtain a product of high ^{239}Pu isotopic purity, but were usually processed after short cooling periods, down to ca. 100 days. The first generation of commercial power reactors in Britain and France were of the gas – graphite reactor type (see Section 3.2). These also applied uranium metal fuels, which were irradiated to burnup levels of ca. 2500 to 4000 MW · d/t, but the cooling periods before chemical reprocessing were increased to a few years.

The first industrial process for plutonium production, the so- called *Bismuth Phosphate Process* (BIPO), had been developed during World War II in the frame of the U.S. Manhattan Project, and was at first performed in a pilot plant at the Clinton Works, Oak Ridge, Tennessee, which later became the Oak Ridge National Laboratory (ORNL). A full-size industrial plant was then constructed at Hanford, Washington, which operated until 1951. The BIPO Process was a batch precipitation process in which the coprecipitation of Pu^{4+} with bismuth phosphate from a nitric acid solution of the fuel was the essential separation step.

All the later industrial processes, both for defense and commercial purposes, were based on *solvent extraction*, a separation technique highly suitable for continuous multi-stage operation, thus offering the potential for high throughput combined with excellent separation efficiency and product yield. The *Redox Process* performed from 1951 to 1966 in the Redox Plant at Hanford in the United States, applied methyl isobutyl ketone ("hexone") to coextract both hexavalent plutonium (oxidized by chromate) and uranium from a nitrate fuel solution. The separation of the two products was performed after reduction of Pu (VI) (hence the name "Redox") to inextractable Pu (III) with "ferrous sulfamate" [iron (II) amidosulfate]. A similar process was the *Butex Process* developed in the United Kingdom, which was applied between 1952 and 1964 in the Windscale I Plant at Sellafield, Cumbria. The extractant, called " butex" or " dibutyl carbitol" (diethylene glycol dibutyl ether) extracts uranium (VI) and plutonium, both as Pu (IV) or Pu (VI), from a nitric acid fuel solution. For uranium – plutonium separation again the inextractability of Pu (III) was utilized.

The *PUREX-Process* which is the sole reprocessing procedure in industrial use today, applies tri-*n*-butyl phosphate (TBP) in a kerosene-type aliphatic hydrocarbon diluent as the extractant for uranium and plutonium. Again the

process utilizes the highly selective extractability of tetra- and hexavalent uranium and plutonium nitrates to separate them from the bulk of fission products in a nitric acid medium, and the plutonium – uranium partitioning is performed by reduction of plutonium to inextractable Pu (III). The PUREX process was developed in the late 1940s by LANHAM and RUNION at Oak Ridge, who also gave it the name PUREX (Plutonium, Uranium, Reduction, EXtraction) [249]. After successful pilot-plant demonstration at ORNL, the process was applied in two large-scale plants at Aiken, South Carolina (Savannah River Plant, operated from 1954), and Hanford, Washington (operated from 1956), and was later adopted worldwide both for military and commercial application. For reviews, see [245–248], [250], [251].

In addition to *aqueous processes* in which the fuel is first dissolved in nitric acid before some type of high-effi-ciency aqueous separation chemistry is carried out, a variety of *nonaqueous* alternatives has been investigated, with the hope of arriving at a simpler and more compact recycle procedure. Most of these processes achieved only a low separation efficiency, i.e., a low decontamination of uranium and plutonium from radioactive fission products, with the effect that the uranium recovered would have been unsuitable for reenrichment, and fuel refabrication would have to be carried out by remote techniques under high shielding. The only high-efficiency separation procedure among the nonaqueous approaches, the *Fluoride Volatility Process*, was based on the volatility of actinide hexafluorides but was hampered by the chemical instability of PuF_6, the high corrosivity of fluorine compounds, and many other drawbacks. None of the nonaqueous procedures could be developed to industrial maturity. For reviews see [248], [252], [253].

5.4.1. Reprocessing of LWR Fuel Elements

5.4.1.1. General Scheme

After discharge from the reactor and pre-cooling on the reactor site, spent LWR fuel elements are transported in shielded containers to the reprocessing plant where they are transferred into an on-site fuel element storage facility for further cooling. Both underwater storage in a cooling pond, and dry storage in air-cooled shielded containers are in common use.

Figure 118. Block scheme of nuclear fuel reprocessing

The chemical processing of LWR fuel elements is usually performed after a total cooling period between 3 and 7 years. This allows the short-lived radioactive fission product and actinide nuclides to decay, while only those with half-lives > 80 d survive to any noteworthy extent. Figure 118 presents a block scheme of the various steps that are carried out in a reprocessing plant. First, the fuel element is disassembled, and the fuel pins are sheared or "chopped" into short pieces ("mechanical head-end"). These pieces are transferred into a dissolver where the uranium oxide fuel matrix is dissolved or "leached" with boiling nitric acid, leaving behind the chopped Zircaloy cladding hulls which are not attacked by the acid ("chemical head-end"). The entire pretreatment is called *shear – leach* or *chop-and-leach process.* Next, the dissolver solution is clarified and transferred to the PUREX solvent extraction plant where uranium and plutonium are separated from fission products, byproduct actinides, and from

each other by countercurrent multistage extraction with 30 % TBP in a kerosene-type diluent. The two products are then further purified, usually by one or two additional cycles of TBP solvent extraction ("tail end"), before they are recycled for conversion into new fuel materials. The fission product waste stream is concentrated by evaporation, and stored as a high-activity waste (HAW) solution in cooled tanks before it is transferred to the waste treatment plant for solidification into a product which can be permanently stored. In a similar manner, solid and liquid medium- (MAW) and low-activity wastes (LAW) are concentrated and solidified for safe long-term disposal. Gaseous effluents from all process stages must be purified from radioactive and chemical pollutants before they are released to the environment.

5.4.1.2. Fuel Composition and Purification Requirements

The composition of a typical irradiated LWR fuel is given in Tables 58 and 59. The fuel selected as example is a Biblis A-type PWR (pressurized water reactor) UO_2 fuel of 3.4 wt % initial ^{235}U enrichment, irradiated to 36 000 MW · d/t burnup, and cooled after reactor discharge for three, five, or seven years. All data were calculated using the KFK KORIGEN code, and are given per tonne initial uranium. Inventories of mass, radioactivity, and thermal power are presented for actinides (Table 58) and fission products (Table 59). Long-term trends for the radioactivity and decay heat of both the fission products and the actinides are shown in Figure 119. The two tables demonstrate that literally "half the periodic table" is formed by fission or neutron capture during fuel irradiation, but they also show that after decay periods of ≥ 3 years, only a relatively small number of nuclides still make an essential contribution to the fuel's radioactivity and thermal power. Whereas for short- and medium-term periods both parameters are dominated by the radioactive fission product nuclides, the long-lived isotopes of plutonium, americium, and neptunium become the dominant factors after prolonged decay times (Fig. 119). This aspect is important with respect to the permanent disposal of the radioactive waste products.

Figure 119. Radioactivity (A) and decay heat (B) of Biblis A-type PWR fuel of 36 GW · d/t burnup as a function of time

The degree of purification which the product values require, is primarily determined by the demand that these can be handled "directly" or "hands-on" in the prereactor fuel cycle facilities into which they are recycled, to avoid the need of heavy shielding and remote operation of these plants. This means that uranium must be decontaminated from both the β,γ-emitting fission products, and the α-emitting transuranium actinides including plutonium, to an activity level equivalent to that of natural uranium in equilibrium with its decay daughters. For plutonium the primary requirement is to reduce the γ emitters to a level corresponding to its own γ and neutron dose rate so that it can be handled in glove-box equipment. In addition, "conventional" impurities such as corrosion products or water and reagent impurities must be restricted in the products. This is particularly true for neutron-absorbing impurities (expressed as the "boron equivalent", i.e., the amount of ^{10}B

having the same neutron absorption capacity as the elements in question), and in the case of uranium for elements forming nonvolatile fluorides which would disturb the UF_6 conversion stage. Typical product specifications resulting from such considerations are given in Table 60.

The so-called *decontamination factor (DF)*, defined as

$$DF = \frac{\text{(impurity : product) before purification}}{\text{(impurity : product) after purification}}$$

which must be attained in PUREX for the radioactive fuel contaminants, is obtained by relating product specifications with fuel composition data as given in Tables 58 and 59. For instance, the uranium represented in Tables 58 and 59 and cooled for 3 years, requires a *DF* of ca. 2×10^6 for γ-emitting fission products and of ca. 1×10^6 for plutonium to meet the specifications of Table 60, whereas for the plutonium the respective figures are ca. 2×10^6 for fission products and 3×10^4 for uranium.

5.4.1.3. Mechanical Head-End

The Zircaloy which is used as the cladding material for LWR fuel pins is not attacked by nitric acid. Therefore, some pretreatment is necessary to remove or at least open the pin cladding to expose the fuel to the acid. Although chemical decladding procedures have been developed and applied on a pilot-plant scale (Eurochemic Plant, Mol, Belgium [254]), the pretreatment in normal industrial use is the mechanical shearing of the fuel pins into short segments of ca. 3 – 5 cm length. The shearing can be carried out either on the fuel element as a whole, or on bundles of fuel pins after previous disassembling of the fuel element. Single-pin shearing is only employed in pilot-scale plants of low throughput.

As a typical example, the head-end facilities of the French UP-3 plant at Cap de La Hague are described in more detail [255]. With a nominal capacity of 800 t uranium per year (4 t uranium per day), UP-3 is, at the time of writing (1991), the largest operating LWR fuel reprocessing plant worldwide. It has two independent head-end lines, each housed in a separate hot-cell complex and equipped with a hydraulic fuel element shear, a dissolver, and a feed clarification unit plus auxiliary equipment such as off-gas purification and solid waste packaging. Each line is designed for the full plant capacity, so that only one unit is in operation at any time while the other is on standby. The fuel element to be processed is transferred by a special conveyor truck from one of the storage ponds via an inclined channel into the reception cell. A bridge crane is used to unload the fuel element from the truck and, after thorough inspection, to carry it over into the shear cell. Here it is loaded into a tipping device connected to the shear, rotated into a horizontal position, and pushed into the shear. The fuel element's foot-end is cut away by the horizontally operated shear blade, and is transferred to a solid waste container. Next, the loosened pin bundle is sheared into segments of ca. 3 cm length which fall down into the dissolver. The fuel element's top-end which is left behind is again discharged to solid waste.

A shear machine must be designed with great care in regard to its maintenance and repair, because most of this must be performed by remote techniques. For instance, the remote exchange of spent shear blades is a frequent routine operation. Direct maintenance can be applied for the hydraulic shear drive which in the UP-3 plant is located in a separate, accessible room outside the hot cell.

5.4.1.4. Fuel Dissolution

The next treatment step is the dissolution of the fuel in nitric acid. The main reason for the use of a nitric acid medium in reprocessing–instead of media such as hydrochloric or sulfuric acids–is the fact that stainless steel can then be used as the construction material for equipment, vessels, and piping, which would not be possible

with the other acids because of their corrosive action.

Chemistry. Uranium dioxide is readily dissolved by nitric acid with the formation of uranyl nitrate and a mixture of gaseous nitrogen oxides. The following reactions contribute to the total turnover [256], [257]:

$$UO_2 + 4\,HNO_3 \longrightarrow UO_2(NO_3)_2 + 2\,NO_2 + 2\,H_2O \quad (6)$$

$$3\,UO_2 + 8\,HNO_3 \longrightarrow 3\,UO_2(NO_3)_2 + 2\,NO + 4\,H_2O \quad (7)$$

$$4\,UO_2 + 10\,HNO_3 \longrightarrow 4\,UO_2(NO_3)_2 + N_2O + 5\,H_2O) \quad (8)$$

The extent to which the two main reactions (6) and (7) contribute is determined by the equilibrium:

$$3\,NO_2 + H_2O \rightleftharpoons 2\,HNO_3 + NO \quad \Delta H = -73\,\text{kJ/mol} \quad (9)$$

Consequently the molar NO_2: NO ratio increases with increasing nitrate concentration and temperature. Reaction (8) is a side reaction which is favored by a high nitric acid (but not nitrate) concentration and a high temperature; under favorable conditions (12.5 M HNO_3, 90 °C) it may contribute as much as 16 % to the total turnover. The dissolution rate is characterized by an induction period of various length, indicating an autocatalytic process. The rate increases strongly with the nitrate concentration and with the temperature up to 90 °C, but it decreases if the temperature is further increased, indicating the loss of a catalyst. The rate also decreases with increased intensity of mixing until a lower rate limit is reached, again indicating the removal of a catalyst from the UO_2 surface. The rate law was found to be:

$$dn/dt = k\,q_0\,(1-n)^{2/3} \quad (10)$$

where n is turnover, t is time, k is rate constant, q_0 is the UO_2 surface at $t = 0$; the term $(1-n)^{2/3}$ accounts for the decrease of the surface with progress of dissolution. Uranium (IV) ions could not be detected as an intermediate in solution despite intense search.

The following reaction mechanism was derived from these observations: during the induction period, an autocatalytic species is formed at the UO_2– HNO_3 interface, which could either be HNO_2, the primary reduction product of HNO_3, or a species in equilibrium with it, such as N_2O_3:

$$2\,HNO_2 \rightleftharpoons N_2O_3 + H_2O \quad (11)$$

This assumption is supported by the fact that the induction period is decreased by the addition of $NaNO_2$, but is substantially increased if a nitrous acid scavenger such as azide ion is added (Eq. 12).

$$HN_3 + HNO_2 \longrightarrow N_2 + N_2O + H_2O \quad (12)$$

Moreover there is direct visual evidence for the formation of N_2O_3 at the UO_2 surface. The catalyst oxidizes U^{4+} in the crystal surface to penta- or hexavalent uranium, and is itself reduced to NO. The higher-valent uranium species formed can escape from the very stable fluorite lattice of UO_2 and is able to transfer into the solution, while NO reacts with HNO_3 under reformation of the catalyst (Eq. 13).

$$2\,NO + HNO_3 + H_2O \rightleftharpoons 3\,HNO_2 \quad (13)$$

This mechanism also explains why PuO_2 is practically insoluble in nitric acid, because the oxidation potential of both HNO_3 and HNO_2 is insufficient to oxidize Pu^{4+} which is bound in the fluorite lattice to a higher oxidation state. However, PuO_2 can be dissolved if a stronger oxidant such as Ce^{4+} or Ag^{2+} is added. A variant is the electrolytic dissolution of PuO_2 in the presence of small amounts of Ce^{3+} or Ag^{+} which act as redox catalysts. Plutonium dioxide can also be dissolved in HNO_3 in the presence of a strong complexant for Pu^{4+} such as fluoride ion, but obviously this reaction proceeds by a totally different mechanism [258], [259].

The dissolution behavior of $(U_{1-x}Pu_x)O_2$ solid solutions in HNO_3 is characterized by a transition from easy solubility at plutonium concentrations $x \lesssim 0.35$ to virtual insolubility at $x \gtrsim 0.40$. As a consequence, the dissolution behavior of UO_2–PuO_2 mixed oxide fuels, the composition of which may vary from a few percent of Pu (LWR – MOX) up to ca. 30 % Pu (MOX for small- to medium-size FBRs), is determined by the chemical state of the material. If the fuel is in the state of a homogeneous solid solution, it will dissolve totally in hot nitric acid; if it is inhomogeneous and contains a major proportion of a plutonium-rich $(U, Pu)O_2$ phase, or of pure PuO_2, it will be only partially soluble,

and a major proportion of the plutonium is retained in the insoluble solids. These plutonium residues could only be dissolved by the aforementioned methods (strong oxidants, complexants). However, for irradiated fuels these would be very inconvenient because fluoride is strongly corrosive to stainless steel, and would require the use of a different construction material, whereas strong oxidants have the drawback that the fission product ruthenium is oxidized to volatile RuO_4 which would escape into the off-gas system. Other potential methods such as dissolution in a strongly reducing acid (e.g., HBr) or in a salt melt (e.g., molten Na_2CO_3) also have obvious severe drawbacks. Thus, it is most important that MOX fuel is fabricated in a way to guarantee that the material is highly homogeneous (see Section 5.3.3.6).

So far only the behavior of unirradiated fuel materials has been considered. In the dissolution of irradiated UO_2 or MOX fuels, small amounts of insoluble, highly radioactive residues are always observed. The mass of these residues increases more than proportionally with fuel burnup, but remains below 1 % of the total fuel mass even with very highly irradiated material. The amount of plutonium retained in these insolubles is generally well below 0.1 % of the total plutonium in the fuel, and thus does not present a loss problem. The composition of the insolubles from as-specified fuels, both UO_2 and MOX, is complicated [260], [261]. Apart from coarse objects such as screws resulting from fuel element shearing, the fines contain materials originating both from the fuel itself, and from the cladding. Thus, particles of metallic or partially oxidized Zircaloy (LWR) or stainless steel (SNR) come from the cladding. The residues originating from the fuel itself are mainly composed (1) of a metallic noble metal phase containing the fission products Mo – Tc – Ru – Rh – Pd which is a primary product formed in the fuel (so-called ε-phase); and (2) of a secondary product generated by reprecipitation of dissolved fission products from the fuel solution in the form of an oxidic material containing mainly Mo – Tc – Ru – Rh – Pd – Te – Zr.

Technical Performance. Fuel dissolution is usually performed as a *batch process*. The dissolver is positioned below the fuel element shear and consists of a vessel fabricated from a highly corrosion-resistant stainless steel or nickel-base alloy, into which a basket, made from the same material, is inserted. The sheared fuel pin segments fall down into the basket which is submersed in nitric acid, and the dissolution is accelerated by heating. At the end of the process the basket is lifted out of the solution, the leached Zircaloy cladding segments retained in it are rinsed with dilute acid, and are then transferred to solid waste. In the design of the dissolver, criticality control plays a dominant role (see Section 5.4.1.11) and is a limiting factor for the dissolver capacity. For large plants, several dissolvers are therefore needed which can be operated in a cycle mode, and a semicontinuous form of operation is thus achieved.

In contrast, each of the two head-end lines of the French *UP-3 plant* is equipped with a *continuous rotary dissolver* (Figs. 120 A and B) [262]. It consists of a stainless steel vessel of critically safe dimensions which holds the nitric acid – uranyl nitrate dissolver solution of average composition 200 – 300 g/L uranium, 2.7 – 3.3 mol/L nitric acid). A Zircaloy wheel with perforated walls, which is subdivided into 12 sectorial compartments, is suspended in the cover of the vessel, such that its lower part submerges into the solution. Both the cover, which also carries all mechanic drives, and the wheel itself, can be remotely removed by a crane for repair or replacement. The fuel element shear which is arranged above the dissolver, delivers the sheared pin segments into a wheel compartment submerged in solution. When the compartment is loaded, the wheel is turned by 30 °, and the next sector is charged with fuel. The speed with which the wheel is turned is rated such that complete dissolution of the fuel in the hot dissolver solution is guaranteed. After several 30 ° turns, the leached cladding segments emerge from the solution, and the residual solution entrained in the hulls can drain out. Finally, when the compartment arrives in an upper position the hulls are discharged via a rectangular gorge into a rinsing vessel, from which they are evacuated by a helicoidal ramp while the rinsing solution is recycled.

5.4.1.5. Feed Clarification and Make-up

Small quantities of insoluble, highly radioactive fine particles which amount to ca. 5 kg per tonne of fuel remain in the dissolver product solution. These must not pass on into the solvent extraction system because here they would contribute considerably to the radiation decomposition of the organic extractant, and to the consequent formation of interfacial "cruds" which can lead to severe operational problems in solvent extraction equipment. Therefore, a highly efficient clarification process which can retain fines with a size down to ca. 1 µm must be carried out. Both filters and centrifuges have been utilized; in modern plants, the trend is in favor of high-efficiency centrifuges.

Before the feed solution is introduced into the solvent extraction system, its uranium and acid

concentrations must be made up to flow sheet specifications.

5.4.1.6. PUREX Process: Chemistry

The basic extraction chemistry of the elements involved in the PUREX process has been the target of many investigations. Reviews can for instance be found in [250], [263], and [264]. In this chapter, only a very general description is given.

Figure 121. Distribution coefficients for uranium, plutonium, and representative fission products in the system HNO_3 – 30 vol % TBP – kerosene as a function of the HNO_3 concentration
——— Trace metal concentration; – – – – – – – In the presence of 100 g/L uranium in the organic phase

Actinide Extraction Behavior [263], [264]. Tri-*n*-butyl phosphate is a strong and highly selective extractant for tetra- and hexavalent actinides from nitric acid media. This property is based on the formation of stable complexes between actinide nitrate and TBP which are soluble in the organic phase. For hexavalent actinides, and especially for uranyl nitrate, the formation of complexes of the composition $MO_2(NO_3)_2(TBP)_2$ is well established. $UO_2(NO_3)_2(TBP)_2$ has been isolated as a low-melting crystalline solid (*mp* $-6\,°C$), and the molecular structure of the triethyl phosphate (TEP) analogue, $UO_2(NO_3)_2(TEP)_2$, has been determined by X-ray diffraction.

In this compound, the trialkyl phosphate is bound to the central uranium atom via its phosphoryl oxygen atom, and the nitrate ion acts as a bidentate ligand. The identity of the complexes formed by tetravalent actinides is less well established. Based on indirect evidence such as the dependence of distribution coefficients on the extractant concentration, the composition $M(NO_3)_4(TBP)_2$ is most often proposed but direct evidence is lacking. Instead, a thorium model compound $Th(NO_3)_4(TMP)_3$ carrying three instead of the proposed two trimethyl phosphate (TMP) ligands has been isolated, keeping the question of the true composition of the M^{4+} complexes in solution unresolved.

Actinide nitrates in oxidation states other than +4 or +6 form less stable complexes with TBP, and hence are much less efficiently extracted. The same is true for most other metal nitrates, including the fission product metals.

The extent to which a species M is extracted into the organic phase is given by the distribution coefficient (distribution ratio) *D*, defined as

$$D\,(\mathrm{M}) = \frac{[\mathrm{M}]_{\mathrm{org}}}{[\mathrm{M}]_{\mathrm{aq}}} \tag{14}$$

where [ ] denotes equilibrium concentrations, and the indices "org" and "aq" denote the organic and aqueous phases, respectively. The distribution coefficient is a function of many parameters, in particular the composition of the aqueous and organic phases. Under typical PUREX conditions, i.e., 20 – 30 vol % TBP in the organic solvent, the distribution coefficient for U (VI) and Pu (IV), which are the normal oxidation states in nitric acid, is < 1 at low HNO_3 concentrations but increases to > 10 at intermediate acidities

until a maximum is reached at about 6 M HNO_3 (Figure 121). It then decreases slightly with further increase of acidity. The order of extractability at room temperature and low to intermediate acidities is U (VI) > Pu (IV) > Pu (VI); a practical consequence for PUREX is that the plutonium oxidation state must be adjusted to +4 for optimum extraction. The distribution coefficient for trivalent plutonium is ca. three orders of magnitude lower, and is similar to that for the other trivalent actinides (Am, Cm) or lanthanides (Figure 121); this offers the basis for U – Pu separation. Pentavalent actinides such as NpO_2^+ are also extracted to only a small extent.

Figure 122. Decrease of distribution coefficients with increased uranium loading of the 30 vol % TBP – kerosene phase.
Aqueous HNO_3 concentration rises from 2 mol/L at 0 % loading to 3 mol/L at 90 % loading [246]

The distribution ratios of the tetra- and hexavalent oxidation states of U and Pu increase with approximately the second power of the TBP concentration in the organic phase if tracer metal concentrations are considered. If the metal concentration is increased to bulk amounts while the TBP concentration is kept constant, a decrease of the distribution ratio is observed because the concentration of "free", i.e., noncomplexed, TBP decreases when the latter is consumed in the formation of metal complexes, see Figure 122, uranium curve. At the same time, and for the same reason, the distribution ratios for foreign metals present in small concentrations will also decrease with increasing "metal loading" of the organic phase, see the plutonium and fission product curves of Figures 121 and 122. If two extractable metals in bulk concentrations are coextracted, they will mutually compete for the extractant, with a mutual decrease of the distribution coefficients. Available data is compiled in [265]. Nitric acid also forms a solvate with TBP, and is therefore extracted into the organic phase to an appreciable extent, where it participates in the mutual competition for the extractant.

A somewhat different presentation of the effect of bulk metal extraction is given in Figure 123 where the organic vs. aqueous equilibrium metal concentrations are plotted. These so-called "equilibrium curves" are a most important tool for the layout of a solvent extraction flow sheet. In the past, such flow sheets were graphically designed by drawing a McCabe – Thiele diagram [267] into the equilibrium curve to determine the number of extraction stages, followed by an iterative refinement, but this procedure suffers from the drawback that only single-component systems can be easily treated with sufficient accuracy. In consequence, computational procedures [268] are currently applied but again the (digitalized) equilibrium curves form the numerical basis for this treatment. An analysis of the uranium curves of Figure 123 shows that at very high aqueous uranium concentrations, the organic phase becomes saturated with metal, and the equilibrium curve levels out. This is to be expected when all TBP has been consumed for complex formation; the upper limit of organic metal loading is termed "maximum loading". In the case of plutonium, however, the theoretical maximum loading cannot be attained; instead, the two-phase equilibrium curve ends before the region of total consumption of TBP is reached. This is due to a phenomenon known as "third phase formation": the organic phase splits into two phases, a heavy one rich in metal and TBP, and a light one rich in diluent, if a certain limit of metal (and acid) loading is exceeded. Third phase formation is quite a common phenomenon in solvent extraction systems;

in particular for metal nitrate – TBP – paraffinic diluent systems, it occurs readily with tetravalent actinides but to a much lesser degree with hexavalent MO_2^{2+} ions. A practical consequence for PUREX is that organic-phase plutonium loadings must be kept well below the third-phase boundary under all conditions of operation because solvent extraction equipment is designed to separate two, not three, liquid phases.

Figure 123. Equilibrium curves for the extraction of uranyl nitrate (A) and plutonium(IV) (B) with 30 vol % TBPdodecane, T = 25 °C
The dashed curve in (B) represents the three-phase limits for plutonium.
a) 0.1 M HNO_3; b) 1 M HNO_3; c) 3 M HNO_3; d) 5 M HNO_3; e) 0.5 M HNO_3

The temperature dependence of the distribution ratios is generally slight; thus, a slight decrease of D for U and Pu is observed with increasing temperature. The tendency to form a third phase decreases with increasing temperature.

Fission Product Extraction Behavior [269]. Particular attention must be paid to those nonvolatile fission products which at the time of reprocessing still contain important amounts of radioactive isotopes (see Table 59). Of these, the alkali and alkaline-earth metals do not form TBP complexes, and are therefore virtually not extracted. The lanthanide(III) nitrates form TBP complexes, similar to their actinide(III) analogues, but these complexes are much weaker than those produced by tetra- or hexavalent actinides. Therefore a high nitrate salt concentration and low acidity combined with a high TBP concentration is needed to extract them efficiently into the organic phase. Under typical PUREX conditions (ca. 3 M HNO_3, 30 % TBP) the trivalent lanthanides and actinides show distribution coefficients nearly three orders of magnitude lower than Pu (IV) or U (VI) (Fig. 121), and are therefore efficiently separated from the latter. The same applies for cadmium and antimony.

More trouble is caused in PUREX by the fission products ruthenium, zirconium – niobium, and technetium, with ruthenium probably the most awkward (for more details, see [269]).

The distribution coefficients of *ruthenium* given in Figures 121 and 122 represent the global extraction behavior of this metal in the extraction section of a first PUREX cycle. Indeed the ruthenium fraction in a fuel solution is not uniform, but consists of a mixture of oxidation states +2, +3, and +4, which all form a variety of nitro and nitrato complexes. Whereas most of these are only slightly extracted by TBP, a few species exist which are highly extractable, notably the neutral or anionic tri- or tetra-nitrato and -nitro complexes of the very stable nitrosylruthenium entity, $RuNO^{3+}$. Since they are preferentially extracted, these species accumulate in the organic TBP phase, and therefore the distribution coefficients during back-extraction operations (scrub and back-wash, see Section 5.4.1.7) are much higher than the "global" values given in Figures 121 and 122. The accumu-

lation of highly extractable species also explains why the ruthenium decontamination achieved in TBP purification cycles is substantially lower than that achieved in the first extraction cycle. Although it is true that these species are in equilibrium with poorly extractable cationic species, the interconversion rates are relatively slow, and equilibrium is not attained during the residence times available in solvent extraction equipment. As can be derived from Figures 121 and 122, a high nitric acid concentration in the aqueous phase and in particular a high uranium loading of the organic solvent help to improve the separation of ruthenium from the product elements. Moreover, the distribution coefficients of most of the ruthenium species decrease with increasing temperature, while the complex interconversion rates increase, with the effect that the formation of poorly extractable complex species is accelerated. Both effects lead to a decrease of the "global" ruthenium distribution ratios with increasing temperature, and therefore it is often recommended to apply a "warm" scrub for improved decontamination from this fission product.

Zirconium-95 (half-life 65 d) and its daughter nuclide *niobium-95* (35 d) are very troublesome in the processing of short-cooled (e.g., FBR) fuel elements, but due to their relatively rapid decay the problems they present diminish greatly with prolonged cooling. The extraction chemistry of zirconium in HNO_3–TBP systems is complicated because Zr^{4+} forms a variety of nitrato – hydroxo – aquo complexes, and nitrato – hydroxo- or oxo-bridged oligomers. The extractable species are believed to be the TBP-disolvates $Zr(NO_3)_4(TBP)_2$ and $ZrOH(NO_3)_3(TBP)_2$ [269]. In contrast to ruthenium, the zirconium distribution coefficient increases with increasing nitric acid concentration (Fig. 121); therefore in a PUREX flow scheme optimized for the decontamination of ruthenium and zirconium, the optimal acidity will be a compromise between the individual requirements of the two [270]. Similar to most other fission products, the extraction of zirconium is suppressed by increased uranium loading of the organic phase (Figures 121 and 122). The factor which dominates the behavior of zirconium in PUREX is however its high extractability by dibutylphosphoric acid, $(C_4H_9O)_2POOH$ or "HDBP," which is formed by radiolytic degradation of TBP. Zirconium is extracted as a bis-dibutylphosphate salt, $ZrX_2(DBP)_2$ (where X^- is NO_3^- or OH^-). This compound has a relatively low solubility both in the organic and in the aqueous phase, and hence it precipitates as a slimy interfacial crud as soon as its solubility limit is exceeded. Secondary radiolysis products of TBP, such as monobutylphosphoric acid, $C_4H_9OPO(OH)_2$ or "H_2MBP," do also contribute to the formation of crud, which has the unpleasant property of absorbing any (radioactive) fine particles present in the solution. Since crud is difficult to remove from extraction equipment, especially from mixer – settlers, it can build up an additional irradiation source for the organic solvent which then accelerates the degradation of TBP and, hence, the formation of more crud, similar to an autocatalytic process. If formed in large amounts, crud can become a serious operational problem by plugging the solvent extraction equipment. This is the reason why fission product zirconium must be closely controlled in PUREX, even though it contains only inactive isotopes after long cooling. Measures to prevent the formation of crud include (1) a highly efficient feed clarification to prevent the transfer of radioactive fine particles from the dissolver into solvent extraction; (2) a high uranium loading of the organic phase and an increase of the aqueous nitric acid concentration to ca. 3 mol/L because it has been found that the formation of Zr – HDBP precipitates diminishes under these conditions; (3) the application of short-residence-time solvent-extraction equipment, i.e., of pulsed columns or centrifugal extractors instead of mixer – settlers, to decrease the irradiation dose to the solvent; and (4) a highly efficient solvent wash after the process, to prevent the build-up and recycle of TBP degradation products with the organic solvent [248].

Technetium, as the long-lived ($t_{1/2} = 2.1 \times 10^5$ a) soft β-emitter ^{99}Tc, the only isotope of practical importance, is not a radiation problem in the PUREX process but instead causes troubles of a different kind. Uranium which is to be reenriched must be highly decontaminated from technetium because it causes operational problems both in the conversion and enrichment processes (see Table 60). Moreover, its control is necessary because due to its long half-life

and high mobility in the environment, it could present a long-term radiation hazard if improperly handled. Finally, if technetium is present in substantial quantities, as is the case with fuels of high burnup, it can cause chemical problems in the solvent extraction process itself. Technetium is stable in nitric acid solution as the heptavalent pertechnetate anion (TcO_4^-). Strong reductants reduce TcO_4^- to Tc^{4+}. Pertechnate alone is moderately extracted by TBP (Figure 121), probably as the trisolvate $HTcO_4(TBP)_3$. The distribution coefficient has its maximum at ca. 0.5 mol/L HNO_3 and decreases with increasing HNO_3 concentration; thus, for typical PUREX extraction conditions (3 mol/L HNO_3, 30 vol % TBP, 30 °C), D(Tc) is ca. 0.1, a value which would not suggest problems in separating it from U and Pu. However, in contrast to other fission products the extractability of TcO_4^- increases substantially if extractable cations such as Zr^{4+}, Pu^{4+}, or UO_2^{2+} are present. The reason is that TcO_4^- can replace NO_3^- in the extracted metal nitrate – TBP complexes, i.e., species of the type $M(NO_3)_3(TcO_4)(TBP)_2$ or $MO_2(NO_3)(TcO_4)(TBP)_2$ are formed. In this way technetium is coextracted with uranium and plutonium in the extraction contactor. In the partitioning contactor a mixture of uranium (IV) nitrate and hydrazonium nitrate is used to reduce Pu (IV) to inextractable Pu (III) (see Section 5.4.1.7) and this reductant also reduces TcO_4^- to inextractable Tc^{4+}, which is thus separated from the uranium and accompanies the plutonium. However, technetium must be prevented from accumulating in the partitioning extractor because Tc^{4+} is easily re-oxidized by nitric acid, and both the nitrous acid and the TcO_4^- formed oxidize the holding reductant hydrazine.

5.4.1.7. PUREX Process: Flow Sheet

The chemical separation process must satisfy two requirements which are contradictory to each other: (1) The recovery of the values, uranium and plutonium, must be very high; a yield of > 99 % is usually demanded. (2) The decontamination of the products from impurities, i.e., the fission products and nonfissile actinides, must be very high; a decontamination factor of $> 10^6$ is usually required. There is no chemical procedure which could fulfill these two requirements in a single step, and this is also true for solvent extraction by TBP (see extraction data in Section 5.4.1.6). The only way to achieve this goal is a multiple repetition of the recovery and purification operations as a multistage, countercurrent process.

Figure 124 presents a basic first-cycle PUREX flow sheet. A "box" in Figure 124 symbolizes a multistage, countercurrent extractor. Auxiliary equipment such as evaporators, tanks, pumps, metering equipment is not shown. The organic solvent stream is symbolized by a dashed line whereas aqueous streams are depicted by solid lines. The designations of the various reagent streams are indicated in ovals. A set of "typical" compositions and flow rates of the various feed and product streams is presented in Table 61. These data do not represent an actual flow sheet as applied in an existing plant, but instead form a sample flow sheet calculated for the treatment of LWR fuel in the basic set of extraction equipment presented in Figure 124. The actual arrangement and sequence of extractors, as well as the compositions and flow rates of reagent streams applied in existing plants, can vary within wide limits [270]. Actual plant flow sheets, as far as they have been published, have been reviewed [271].

The organic solvent stream which cycles through the various contactors, is typically composed of 30 vol % TBP in a paraffinic diluent, but lower extractant concentrations (20 or 25 vol % TBP) are applied in a few plants. Facilities specially designed for the processing of highly enriched uranium fuels (e.g., from research and material test reactors) apply much lower TBP concentrations, typically between 2.5 and 7.5 vol %. The diluent is a paraffinic hydrocarbon mixture of approximately C_{12} average chain length; both straight-chain (e.g., *n*-paraffin mixtures $C_{10} - C_{13}$) and branched-chain formulations (e.g., hydrogenated propylene tetramer, HPT) are applied [270], [272]. These diluents are characterized by relatively high boiling and flash points, and by a low density, making the organic phase the lighter phase of the two-phase extraction system.

The high-activity feed solution has a typical composition of ca. 1 mol/L of heavy metals (i.e., uranium plus plutonium) and 3 mol/L HNO_3. It is metered into the middle of the *first contactor*, designated "A" in Figure 124, and flows

Table 61. Sample flow sheet for a LWR PUREX extraction cycle as outlined in Figure 124 (calculated with KFK-VISCO)

Extractor	Stream	Composition	Relative Flow

countercurrently to the organic solvent which is introduced into the lowest extraction stage of the A contactor. At the other end of the contactor an aqueous "scrub" stream is introduced which joins the aqueous feed at the feed stage. The solvent extracts uranium and plutonium in the extraction section, while most of the poorly extractable fission products are rejected. The small fraction of fission products which is co-extracted, is scrubbed out of the organic phase in the scrub section of the A contactor. Flow rates are arranged such that the *organic product stream* which exits from the scrub section is loaded with uranium and plutonium to ca. 70 % of the maximum theoretical loading, i.e., to a heavy-metal concentration of ca. 90 g/L. The *aqueous fission product HAW stream* which exits from the extraction section of the A extractor is sent to an evaporator for concentration, and is then intermediately stored as a liquid HAW concentrate (HAWC) before being solidified into a glass for permanent disposal.

The organic product stream leaving the A contactor is routed into the middle of the *second*, or "*partitioning*", *contactor* (B in Fig. 124), where plutonium is separated from uranium. This is achieved by introducing an *aqueous reductant stream* into the organic exit stage which flows countercurrently to the organic stream. Pu^{4+} is reduced to inextractable Pu^{3+} which transfers into the aqueous phase. The small proportion of uranium which is costripped with Pu^{3+} according to its extraction equilibrium is scrubbed out of the aqueous phase by a small solvent stream (" *organic scrub*"), which is introduced into the aqueous outlet stage of the B contactor.

Figure 124. PUREX process flow sheet
For explanations see text.

The reductant originally developed for the PUREX process was iron(II) amidosulfate ("ferrous sulfamate", FeSA) dissolved in dilute nitric acid, where the Fe^{2+} acts as the reductant for Pu^{4+} and the amidosulfate anion serves as a scavanger for nitrous acid (Eq. 15):

$$H_2NSO_3^- + HNO_2 \longrightarrow HSO_4^- + N_2 + H_2O \qquad (15)$$

Nitrous acid which is a strong oxidant for both the Fe^{2+} and the Pu^{3+} is formed by radiolysis of HNO_3 primarily in the A contactor, but it is extracted by TBP and thus transferred into the B contactor. A large molar excess of the reductant, typically 6- to 10-fold, must be used to guarantee a 100 % recovery of plutonium. Since iron(II) is not extracted by TBP, the reductant is introduced into the end stage of the B contactor ("Reductant 1" in Fig. 124). The disadvantages of FeSA are (1) that a large amount of (inactive) iron is introduced into the process which ends up in the medium-active process waste, thus adding to the processing and storage costs of this material; and (2) that the sulfuric acid generated by decomposition of sulfamate (Eq. 15) is highly corrosive to stainless steel equipment.

Currently uranium(IV) nitrate stabilized by hydrazonium nitrate as the nitrous acid scav-

anger (Eq. 16) is employed as reductant in most LWR reprocessing plants. Uranium is a process-inherent material, and hydrazine is easily oxidized to gaseous products, thus both components do not increase the amount of waste generated, and they are not corrosive.

$$N_2H_5^+ + 2\,HNO_2 \longrightarrow N_2 + N_2O + 3\,H_2O + H^+ \qquad (16)$$

Due to the fact that uranium(IV) is extracted by TBP, the reductant cannot be introduced into the end-stage of the extractor; instead, a "split" reductant stream is employed, i.e., the $U(NO_3)_4$ is introduced near the organic feed-stage ("Reductant 2" in Figure 124) while a stream of the stabilizer solution is introduced into the end-stage ("Reductant 1" in Figure 124). As in the case of ferrous sulfamate, a large stoichiometric excess of the reductant is needed for 100 % recovery of plutonium.

The uranium(IV) reductant solution is normally prepared by electrochemical reduction of an aqueous uranyl nitrate – hydrazonium nitrate solution. An elegant alternative is the direct in-line electroreduction of plutonium in the partitioning extractor itself. In this process which was developed by Karlsruhe's Institut für Heisse Chemie [273], the extractor is equipped with cathodes made from an electrochemically inert material, e.g., titanium. For the anodes platinum-plated titanium or tantalum is used. There is no need to separate the electrode compartments by a diaphragm because the anodic reoxidation of U^{4+} is strongly inhibited. Both electrochemical mixer – settlers and pulsed columns have been designed and operated [274] (see Section 5.4.1.9). The aqueous reductant stream is simply a dilute hydrazonium nitrate – nitric acid stabilizer solution which is introduced at the "Reductant 1" position of Figure 124. Current densities are controlled such that all Pu^{4+} is reduced to Pu^{3+}, and an additional small excess of U^{4+} is generated which acts as the holding reductant.

Other reductants, and separation methods based on complexation instead of reduction of Pu^{4+}, have been investigated but have not so far found application in a commercial plant. For a review of the chemistry and performance of U – Pu partitioning, see [275].

The aqueous plutonium product stream leaving the B contactor is routed to a *reoxidation unit* (not shown in Fig. 124) where Pu^{3+} is oxidized to Pu^{4+}, while the $N_2H_5^+$ is at the same time oxidized to N_2 and N_2O. Both chemical oxidation by $NaNO_2$, gaseous NO_2, or liquid N_2O_4, and electrochemical reoxidation by the so-called ROXI process [273], [274] are used. The plutonium is then further purified by a PUREX purification cycle or some other process (see below). The organic uranium product stream coming from the B contactor is routed into the *back-extraction* or *"strip" contactor* (C in Fig. 124) where the uranium is back-extracted into a stream of slightly acidified water. The C contactor is usually operated at ca. 50 °C because the U distribution coefficient decreases with increasing temperature. The aqueous uranium product stream is then sent to final purification.

The stripped solvent leaving the C contactor must be separated from degradation products formed by radiolytic and chemical attack before it is recycled. The accumulation of degradation products would lead to a rapid deterioration of solvent performance, characterized by a decrease of product decontamination, increased retention of actinides and fission products with subsequent product losses to waste streams, poor phase disengagement, and finally, the formation of radiolytic cruds [272], [276].

Dibutyl- and monobutylphosphoric acid can be removed from the solvent by an alkaline wash which converts them into water-soluble alkali salts. The *wash contactor* (W in Fig. 124) is normally designed as a mixer – settler with internal aqueous recycle which permits operation at a high organic to aqueous flow ratio. Sodium carbonate is generally used as the alkaline scrubbing agent because carbonate acts as a complexant for uranium and plutonium and thus prevents the precipitation of retained heavy metal traces. Unfortunately most of the soda is consumed by the residual nitric acid carried by the solvent, and the sodium nitrate so formed adds a serious burden of inactive solid material to the aqueous medium-active waste stream leaving the wash contactor. Therefore "hydrazine carbonate", i.e., a hydrazine solution saturated with carbon dioxide up to a molar ratio of approximately 2 : 1, was later proposed as the washing agent because the $N_2H_5^+$ ion can be easily oxidized to gaseous nitrogen in a ROXI-type electro-oxidation cell [277].

Although di- and monobutylphosphoric acids are the main products of solvent degradation, a

large variety of minor products are formed by radiation-induced reactions of both the TBP and the diluent [272], [276]. Some of these also form complexes with fission product or actinide metals, but cannot effectively be washed out of the solvent by aqueous alkaline solutions because they contain long- chain aliphatic groups, and their alkali salts are therefore not water-soluble [276]. In consequence they accumulate slowly in recycled solvent, and are a major factor limiting its lifetime.

The sequence of operations as presented in Figure 124 has been implemented in this basic form in only a few existing plants while modifications have been applied in most others. In many cases the extraction – scrub contactor (A) is followed by an additional *scrub contactor* (often called "S") in which the metal-loaded solvent undergoes a second fission product scrub before entering into the partitioning system. The scrub section of the A contactor is operated at increased acidity for crud prevention and improved removal of ruthenium while the S contactor is operated at lower acidity, which improves the removal of zirconium and also minimizes the amount of nitric acid which is carried by the solvent into the partitioning system. Decontamination of ruthenium can be further improved if the S contactor is operated at increased temperature. The aqueous scrub stream leaving the S contactor is routed into the scrub section of the A contactor where it joins the A-scrub stream introduced there.

The partitioning contractor B which comprises a reduction section and an organic-scrub section, is often split into two separate contactors. The main reason is that the flow rate of the organic phase is quite different in the two sections, so that two tailor-made contactors can be expected to give better performance than a single unit.

In a few plants, uranium – plutonium partitioning is not performed at all in the first extraction cycle but instead is displaced into the second extraction cycle. In such a case the high-activity cycle is designed as a "codecontamination" process comprising the joint extraction, scrub, and back extraction of plutonium and uranium.

5.4.1.8. PUREX Process: Product Purification

The fission product decontamination factors achieved in the first PUREX cycle are normally of the order of several 10^3. Therefore, uranium and plutonium must undergo additional purification operations in order to meet specifications.

Uranium. Uranium is generally purified by sending it through one or two additional PUREX extraction cycles. However, since most of the plutonium has already been separated from the uranium (except in plants where second-cycle partitioning is performed), and because the fission product radioactivity level is much lower, the uranium purification cycles can be somewhat simplified as compared with the high-activity cycle. Moreover, the purification operations can be tailored for the specific removal of obstinate contaminants which have not been satisfactorily separated in the first cycle, e.g., neptunium [266], [278], [279].

A uranium purification cycle is usually designed as a simple extraction – scrub – backwash cycle comprising two contactors termed 2D (extraction – scrub) and 2E (backwash). The 2D contactor can be operated with either a "concentrated" or a "dilute" flow sheet. In the first case, the first- cycle product solution is concentrated in an evaporator to a uranium concentration of ≥ 1 mol/L before it is routed into the 2D contactor. In the second case, the first- cycle product solution is acidified and then routed directly into this contactor. Flow sheet conditions are in both cases arranged so that a high solvent loading is attained. A small amount of a reductant such as ferrous sulfamate or uranium(IV) nitrate – hydrazonium nitrate is added to the 2D contactor feed to reduce traces of Pu^{4+} to inextractable Pu^{3+}. Neptunium, if present, is rapidly reduced to inextractable Np (V) but only slowly to Np (V) which is moderately extractable. Thus, neptunium decontamination is in most cases only moderate, but tends to be higher with a "dilute" flow sheet.

The second-cycle uranium product is often clean enough to meet product specifications. It is then usually routed through a *fixed-bed column of silica gel* for clarification, and in addition this treatment removes any residual zirconium – niobium by sorption. Other plants,

in particular those treating high-burnup LWR fuels, prefer to incorporate a *third PUREX cycle* for final uranium purification. In this case, residual neptunium can be specifically removed by adding enough nitrous acid (either in the form of $NaNO_2$ or of liquid N_2O_4) into the feed solution so that inextractable Np (V) is stabilized.

The final uranium product solution generated in the PUREX process is concentrated by evaporation to a uranium concentration of ca. 400 g/L. Its further treatment is dependent on the destination of the material – direct recycle into MOX fuel fabrication, or conversion to UF_6 for reenrichment (see Section 5.2.5).

Plutonium. Various methods such as anion exchange or solvent extraction by a long- chain tertiary amine nitrate solution have been used for the final purification of plutonium, but all modern plants have reverted to one or two additional cycles of TBP extraction [251], [270], [271]. After reoxidation to Pu^{4+} and reacidification, the first- cycle plutonium product is routed into the *second-cycle A contactor* for extraction and scrub. Any uranium present is coextracted into the organic solvent. As discussed in Section 5.4.1.6 the flow sheet must be designed so that the plutonium loading of the organic phase remains well below the three-phase boundary under all conditions of operation. Due to the moderate loading of the organic phase which can thus be tolerated, fission products are extracted much better than under high-loading conditions, and consequently the decontamination which can be attained in a plutonium purification cycle is lower than that in a uranium cycle.

The back extraction of plutonium cannot easily be performed with warm dilute nitric acid because plutonium(IV) tends to hydrolyze irreversibly with the formation of polymeric species under these conditions [280]. Therefore, the organic plutonium product stream leaving the 2A contactor is routed to a *B-type contactor* where plutonium is reduced to Pu^{3+} and back-extracted. Reductants used are ferrous sulfamate, uranium(IV) nitrate – hydrazonium nitrate, or as a novel development, hydroxylammonium nitrate stabilized by hydrazonium nitrate [281], [282]. The latter reductant must be operated at increased temperature to overcome the relatively low reaction rate of hydroxylamine with Pu^{4+}. The most advanced technique is, however, the direct electrochemical reduction of plutonium in the 2B contactor itself [273], [274] which has been applied in the WAK pilot reprocessing plant at Karlsruhe, Germany.

The way in which the residual uranium present in the 2A contactor product stream is treated, depends on the specifications determined for the plutonium. Material which is recycled into *power reactor MOX fuel* must not be purified from uranium to a high degree. In this case, the organic scrub section is omitted from the 2B contactor, and the flow sheet is designed so that most of the uranium is costripped with the plutonium. If, however, specifications demand a uranium-free product, the flow sheet must be designed so that the uranium leaves the 2B contactor with the solvent stream, which is most easily achieved by incorporating an organic scrub section. The uranium-bearing solvent is then either stripped in a 2C contactor, analogous to the first-cycle flowsheet presented in Figure 124, or it is routed back into the first-cycle C contactor where it is costripped with the uranium main product. Alternatively, if the uranium content is low and must not be recovered, the solvent can be routed directly into the soda wash system where the uranium is stripped as a carbonate complex.

A third plutonium purification cycle, if present in a plant, is more or less a duplication of the second cycle. The final plutonium product solution is evaporated down to a concentration of ca. 200 g/L, and is then transferred to a MOX fuel refabrication plant either directly as a concentrated $Pu(NO_3)_4$ solution, or as solid PuO_2 after precipitation as the oxalate and subsequent calcination.

5.4.1.9. PUREX Process: Extraction Equipment

For a review of extraction equipment for various applications see Liquid – Liquid Extraction, Chap. 3. Equipment to be used in a reprocessing plant must be simple and robust so that a minimum of maintenance is required. So far, pulsed sieve-plate columns, box-type multistage mixer – settlers, and centrifugal contactors have been applied [283].

Mixer – settlers have given satisfactory performance in plants where low-burnup fuels are treated, but difficulties were encountered in the

processing of high-burnup power reactor fuels. Because of the long residence time in a mixer – settler the organic solvent is exposed to a high radiation dose particularly in first-cycle extraction, which promotes the formation of solvent radiolysis products and, consequently, of interfacial crud. Crud tends to accumulate preferably at the quiescent aqueous – organic interface in the settler chambers, which can ultimately cause hydraulic failures due to clogging of ports and weirs. Although this effect can be counteracted by proper feed clarification and by chemical flow sheet optimization, mixer – settlers are no longer used as the first-cycle A contactor in modern LWR fuel reprocessing plants; they can, however, be used in downstream sections of the process.

Pulsed sieve-plates columns offer the advantage of a lower residence time, in particular of the disperse phase, which makes crud formation less probable. If formed, crud has less possibilities of accumulation because there is only a single quiescent interface, and it can be more easily flushed out. In addition, columns are of a simple and robust design, and they can more easily be adapted to criticality-safety conditions (see Section 5.4.1.11). These properties make the pulsed sieve-plate column a first choice both for the high-activity cycle and for plutonium purification. A certain disadvantage is the large height of a column, and the consequent hot-cell height requirement. The detail design of pulsed columns for PUREX plants is still mostly based on experience; "typical" dimensions are: plate spacing, ca. 50 mm; free plate area, ca. 20 – 30 %, pulse amplitude, ca. 20 – 25 mm, pulse frequency, ca. 40 – 90 min^{-1}. Sieve plates have been designed both with simple holes, or with nozzles, and good results have been reported for a "crown-and-disk," or "disk-and-doughnut," arrangement of unperforated plates [284].

Two designs of *centrifugal contactors* have so far been applied in a reprocessing plant. In the Savannah River 221 F Plant in the United States, the first- cycle A mixer – settler (24 stages) was replaced in 1966 by a bank of 18 single-stage centrifugal contactors developed on-site, which have since given very satisfactory service [281]. Operating characteristics for the centrifugal contactors are: rotational speed, 1745 min^{-1}; centrifugal separation force, 300 – 500 g; dynamic liquid volume, 15 L per stage; total liquid flow, 38 – 250 L/min. Unfortunately, no experience with high-burnup fuel is available so far for this attractive contactor type. For further informations and illustrations, see [281], [283].

The French UP-2 plant at Cap de la Hague, originally designed for the processing of low-burnup gas – graphite reactor fuel, was modified in 1976 for the reprocessing of high-burnup LWR fuel [285]. Among the modifications made in the solvent extraction section was the installation of a *ten-stage Robatel centrifugal extractor* (→ 6. Liquid – Liquid Extraction, Chap. 3.1.5.), [283] in front of the original A mixer – settler, to prevent the main fraction of the fission products from entering into the mixer – settler line. A third uranium purification cycle, equipped with similar centrifugal contactors, was also installed. Although details have not been published, there are indications that clogging of the extractor outlet by accumulated solids has sometimes been a problem [285], which would be in line with the results of inactive tests performed in the United States and Germany [283]. Also the fact that in the new UP-3 plant centrifugal contactors have not been incorporated might be taken as an indication that the relatively complicated multistage design was not fully satisfactory.

A = Anode duct, S = Stirrer duct
a) Mixer chamber; b) Stirrer; c) Settler chamber; d) Anode; e) Cathode

For the realization of electrochemical PUREX techniques, both mixer – settlers and pulsed sieve-plate columns have been developed [274]. The *electro-mixer – settler* (Figure 125) is constructed from a corrosion-resistant material such as titanium, and the extractor body which acts as the cathode is grounded. The anodes, made from platinized tantalum or titanium, are installed in the settler chambers where the electro-reduction takes place. The anode area is made much smaller than the cathode area to keep anodic re-oxidation of Pu^{3+} low. In 1980 a 12-stage unit of this design was installed in the plutonium purification cycle of the German WAK pilot reprocessing plant at Karlsruhe as the back-extraction (2 B) extractor, and in 1984 a similar 9-stage unit was installed as the first- cycle partitioning (1 B) contactor to replace the former uranium(IV) nitrate partitioning process. Both units have performed very satisfactorily up to the end of WAK's operation in 1990.

The *electro-pulsed column* (Fig. 126) enables a particularly elegant design by using both the column tube and the sieve plates as the cathodes, thus accounting for ample cathode area. The central rod, spaced from the sieve plates by ceramic insulator rings, is made the anode. The same construction materials as for the mixer – settler can be used. Obviously, such a column must be operated in the aqueous- continuous mode to provide electric conductivity. A semi-industrial-scale unit was operated both with first- cycle partitioning and with plutonium purification flowsheets in the Plutonium Test Facility (PUTE) at Institut für Heisse Chemie, Karlsruhe, with a performance even superior to that of the mixer – settler.

An *electrochemical re-oxidation (ROXI) cell* used for the re-oxidation of plutonium(III) and/or hydrazine solutions, is shown in Figure 127. In this very compact design, the anode area must be made large in comparison to the cathode to provide for efficient oxidation. Again, the body of the apparatus is made the cathode which is connected to ground. The anodes are arranged as a compact package of platinized metal grids which are placed into the electrolyte channel. The latter is meander-shaped to suppress axial mixing, and to provide a cross flow of liquid and anode gas resulting from hydrazine oxidation. ROXI cells have been very successfully operated both in the WAK pilot plant and in the PUTE facility.

5.4.1.10. Off-Gas Purification

The retention of radioactive and chemical pollutants from the gaseous effluents of a fuel reprocessing plant is of similar importance as the treatment of liquid and solid radioactive wastes. However, while the latter can be intermediately stored in buffer stores and then treated in more or less independent facilities, the process and cell-ventilation off-gases must be treated directly and unbuffered. Consequently, the off-gas purification procedures must be integrated into the main processes, which means that a particularly high degree of reliability and availability is required for them.

Pollutants carried by the off-gas streams originate from three sources:

1) *Gaseous or highly volatile fission product elements or compounds* are released from the fuel during shearing and dissolution. The element of main concern is *iodine*, with the radioactive isotopes ^{129}I ($t = 1.7 \times 10^7$ a) and

^{131}I ($t = 8.05$ d); the latter isotope is only important if fuel is treated after cooling times of less than 6 months. Iodine and its compounds can distribute between gaseous, aqueous, and organic-liquid phases, and so the element tends to "smear" over most gaseous and liquid streams of a plant if no countermeasure is taken. In consequence, procedures were developed to force the iodine efficiently into the dissolver off-gas stream, and so to prevent it from penetrating into downstream processes. *Krypton*, with the radioactive isotope ^{85}Kr ($t = 10.8$ a), is 100 % released into the head-end off-gas stream. Although ^{85}Kr is one of the major radiation sources in medium-cooled fuel, it is not routinely retained in present reprocessing plants because of its low contribution to the total human radiation burden. The ternary fission product *tritium* ($t = 12.3$ a) is partially released during dissolution as tritiated water, HTO; another fraction remains firmly bound, as zirconium hydride, in the Zircaloy cladding of LWR fuel pins. Part of the HTO enters the off-gas streams as water vapor but due to its low concentration, no special retention measures must be taken. Moreover, the release of tritium with the gaseous effluents can be minimized if tritiated water is confined to the high-activity portion of a plant. To this end, tritiated water that enters the PUREX first-cycle A contactor with the high-activity feed and distributes into the organic solvent which is scrubbed from the latter by using tritium-free acid as the scrub solution. The HTO is thus forced into the HAW stream, and the tritiated acid recovered during HAW concentration is re-used exclusively as dissolver acid, but is not applied for the make-up of downstream reagents. Finally, ^{14}C ($t = 5730$ a) which is produced in LWR fuel in very minor amounts both by ternary fission and by neutron activation of nitrogen and oxygen, is released as $^{14}CO_2$ during fuel dissolution but again no special measures must be taken for its retention.

2) *Radioactive dusts* arise in the fuel element shearing process, and *radioactive aerosols* are produced from liquids by operations such as reflux boiling, evaporation, air agitation, and transfer by air-lift or steamjet.

3) *Chemical pollutants* of concern are the nitrous oxides which are predominantly produced during fuel dissolution.

Head-End Off-Gas Stream. By far the highest radioactivity level is present in the relatively small head-end off-gas stream produced in the shear – leach process. It contains most of the total inventory of volatile fission products, and the aerosols carried by it contain high concentrations of $\beta-\gamma$-emitting fission product nuclides in addition to the α-emitting actinides which form the main radioactivity in downstream off-gases. Consequently it is separately treated in a series of high-efficiency purification steps which are schematically presented in Figure 128.

Figure 127. ROXI reoxidation cell as operated in the WAK pilot processing plant, Karlsruhe [274]
a) Electric feed; b) Anode; c) Insulator; d) Cathode

The gas stream is first routed through a washing tower where nitrous oxides, acid vapors, and aerosols are scrubbed by dilute nitric acid at near room temperature. The spent scrub acid is recycled into the main process to avoid an extra waste stream. The gaseous effluent is passed through a sequence of regenerable glass-fiber filters followed by non-regenerable high-efficiency par-

ticulate absorber (HEPA) filters for the precipitation of residual radioactive aerosols. The regenerable filters are regenerated by periodic flushing with nitric acid, while the HEPA filters must be periodically replaced.

Iodine [286] is retained by high-efficiency solid sorption processes based on the formation of silver iodide. The sorbent used is either a silver nitrate-impregnated silica gel or a silver zeolite of high specific surface area. The gaseous effluent from the filter line is preheated and passed through a fixed bed of the sorbent which is operated at ca. 150 °C. A residence time of < 1 s is sufficient for > 99.9 % retention of iodine, including organic iodine species which are formed by reaction of iodine with shear machine grease and with organic impurities in the dissolver acid.

As mentioned before, radioactive *krypton* is not routinely retained in present plants, but in view of potential future requirements, low-temperature separation processes have been developed to the demonstration stage [287]. The most promising procedures are kryogenic rectification as demonstrated at the Tokai Mura Reprocessing Plant in Japan, and low-temperature absorption in coolant R-12 (dichlorodifluoromethane) as developed at Karlsruhe, Germany [288]. In both cases, the inactive fission noble gas xenon is automatically co-separated, and could be recovered as a potentially valuable material. Radioactive ^{85}Kr has also special technical applications.

Downstream Process and Cell-Ventilation Off-Gases. The much larger volumes of downstream process and cell-ventilation off-gases are much less radioactive than the head-end off-gas stream, and can be adequately purified by simpler procedures. They are normally processed through an acid scrubber and on through a filter line for aerosol retention. The need for routine retention of iodine can be avoided if this fission product is prevented from entering into downstream solutions by proper treatment in the dissolution and feed pre-treatment stages. A particularly efficient procedure [289] eliminates iodine traces from the clarified dissolver product by heating it close to the boiling point, adding inactive potassium iodate for isotopic dilution, blowing nitrous oxide gases through the solution to reduce nonvolatile species such as iodic acid to volatile elemental iodine, and combining the off-gas produced in this treatment with the dissolver off-gas stream. The downstream off-gas purification system must then only provide for emergency iodine retention to counteract any failure of the head-end off-gas system.

5.4.1.11. Nuclear Safety

In wide parts of a reprocessing plant, radiation protection requirements are determined by the highly penetrating gamma radiation. Alpha and beta particle radiation is much less penetrating and, hence, much easier to shield, while the neutron radiation, although highly penetrating as well, accounts in most instances for only a minor fraction of the total radiation dose rate. To provide protection against gamma radiation, the respective process equipment is enclosed in a highly shielded hot cell, with the consequence that this equipment must be remotely operated [290], [291].

The shielding material most widely used for industrial hot cells is reinforced heavy concrete. Lead or steel shielding is applied for smaller units, such as analytical cells, and for special hot-cell accessories such as wall penetration plugs used for the conveyance of process media, electric ducts, etc. Viewing is provided by shielding windows made from special high-density lead glass. In-cell operations are performed by remotely operated tools such as master – slave manipulators or crane-supported heavy-duty tools. To prevent the penetration of radioactivity into or through the cell walls, these are often sealed with a dense stainless steel liner. Cell ventilation is provided to remove radioactive gases and dusts, and chemically corrosive or explosive gases and vapors, and a staggered sequence of slight underpressure is maintained inside the hot cells and the surrounding buildings so that no uncontrolled air flow out of the radioactive zones into control areas or into the environment can occur.

Remote operation of the process means that all equipment used must be extraordinarily reliable, must require a minimum of maintenance, and must be controlled remotely. One of the many consequences is, for instance, that apparatus equipped with mechanically moving parts is avoided wherever possible, e.g., air-lifts or steam jets are preferred against mechanical pumps for liquids transfer. If mechanical components can-

not be avoided, these are arranged outside the hot-cell whenever possible.

For *maintenance and repair of hot-cell equipment*, two principal concepts known as "direct" and "remote" are available. *Direct maintenance* means that the repair work is done hands-on by personnel entering into the hot-cell. This is only possible after remote decontamination of the equipment and cell structure from its radioactive inventory so that the radiation dose rate inside the hot-cell is reduced to a level permitting access by man. Cell decontamination is tedious and time-consuming work which normally means that the process area concerned is shut down for many months, if not years. In order to limit the expenditure of manpower and down-time, a hot-cell plant designed for direct maintenance is therefore sub-divided into many single cell units sealed and shielded against each other, each of which houses a selected portion of process equipment. "Critical" equipment is often duplicated to gain redundancy. The equipment must be positioned in a way to enable easy access, and remotely operated tools are provided for auxiliary work and for decontamination.

In a plant designed for *remote maintenance*, defective equipment is replaced exclusively by means of remotely operated tools. Examples of remote-maintenance facilities are the Savannah River PUREX Plant at Aiken, South Carolina, and the Hanford PUREX Plant at Hanford, Washington [292–294]. Radioactive equipment is mounted in one or two large, concreteshielded, window-less cell buildings called "canyons". Connections from vessels to the permanently embedded piping are made via remotely operated connectors or "jumpers". The plant is serviced by a bridge crane travelling along the canyon which is operated from a highly shielded cab. The operator views the canyon equipment through a remote optic system, and the jumpers are disconnected or connected by tools carried by the crane. This technique requires that very close tolerances are maintained on the location of wall nozzles, vessel supports, positioning guides, and other cell appurtenances, and the same precision must be attained in the fabrication of the process equipment. Failed equipment is transported by crane to a remotely operated, shielded maintenance facility where it is first decontaminated, and then either repaired for reuse, or dismantled for waste disposal.

Many improvements of the original concept have been made. An important development was the arrangement of process equipment in standardized modules or "racks," which can be replaced by crane as a whole, as it was first applied in the Plutonium Reclamation Facility at Hanford. Another step forward was the development of remotely operated television equipment which allows the remote control of in-cell cranes and similar devices, and thus eliminates the need of a crane operator present inside the high-level area.

In modern commercial plants, a *combination of remote and direct maintenance* is often applied. The main advantage of remote maintenance in a single large cell is that failed equipment can be readily and rapidly replaced, keeping plant downtime and associated profit losses low. Its disadvantage is its distinctly higher investment cost. Thus for a cost-optimized plant, remote maintenance is restricted to high-level areas where equipment requiring frequent maintenance (e.g., fuel element shear), or known to have a limited lifetime (e.g., dissolvers, evaporators, filters, pumps, etc.), is located, while direct maintenance is chosen for long-life accessories such as pulse columns, and for low-level process areas. A fine example of a modern plant designed along these lines is the UP-3 plant at Cap de la Hague, France [295].

Criticality Control [296], [297]. As outlined in Sections 1.3.8 and 1.3.9, criticality is characterized by a self-sustained fission chain reaction. It is accompanied by the release of a large amount of energy, and by the emission of penetrating radiation, especially neutron and gamma radiation. In a plant where fissile material is handled, protection against the occurrence of a criticality excursion must therefore be provided. Generally speaking, such a plant must be designed and operated such that under all circumstances of normal and abnormal conditions, criticality can never occur. Basically the following principles can be used for criticality prevention:

1) *Mass Control.* The total inventory of fissile materials handled in a closed process, or process section, is limited to an amount smaller than the minimum critical mass of that material, e.g., the minimum critical mass for (hy-

Figure 128. Scheme of a typical head-end off-gas purification system

pothetical) homogeneous $^{239}Pu-H_2O$ mixtures is 531 g plutonium.

2) *Concentration Control.* The fissile materials concentration is limited so that the minimum critical concentration cannot be attained or exceeded under both normal and abnormal operation conditions; e.g., the minimum critical concentration for homogeneous $^{239}Pu(NO_3)_4-H_2O$ mixtures of infinite volume is 7.8 ± 0.3 g ^{239}Pu per liter.
3) *Geometric Control.* The dimensions of a vessel containing fissile material are limited to values below the minimum critical dimensions for said geometric solid containing said fissile material; e.g., the minimum critical diameter of a straight cylindric tube of infinite length, filled with a $^{239}Pu(NO_3)_4-H_2O$ mixture of arbitrary concentration, is 16.28 cm.
4) *Poisoning Control.* In the PUREX process a neutron absorber can either be attached to the solution as a soluble component (*homogeneous poisoning*), or it can be attached to the process vessel holding that solution as a solid construction component (*heterogeneous poisoning*). In either case it is important that the physical presence of the poison is regularly verified, e.g., by continuous monitoring of a homogeneously poisoned solution, or by repeated testing of a heterogeneous poison structure.
5) *Administrative Control.* Administrative control procedures play an important role in criticality prevention, and are manifold in number and character. Consider, for instance, the transfer of a solution which is normally fissile-free but might contain fissile material under abnormal operation conditions, from a critically-safe vessel to a vessel of non-safe geometry. The two vessels will be safety-locked against each other to prevent unintentional transfer, and unlocking for transfer will be authorized only after previous analytical verification of the absence of fissile material.

In an industrial-scale plant where large inventories of fissile material must be handled, criticality control is generally achieved by a combination of the aforementioned principles. Mass limitation alone will only have limited use because of the small size of a critical plutonium mass, but can be applied with advantage in areas where only small batches must be handled, such as the analytical laboratory. Mass limitation in combination with geometric and/or poisoning control is used in areas where batch procedures are operated, such as a batch dissolver. For a continuous process such as solvent extraction, geometric control in combination with poisoning can often be applied with advantage. Gadolinium nitrate has been considered as a *homogeneous poison* for PUREX but its disadvantages are that this expensive material is lost with the high-level waste, and that it is not extracted into the organic solvent phase, so that fissile plutonium and poison would separate in case of an accidental contactor shut-down. *Heterogeneous*

poisoning of a geometrically limited apparatus is therefore often more straightforward. Consider for instance the case of a sieve-plate column for plutonium extraction which is geometrically eversafe up to a diameter of ca. 16 cm (see point 3 in the list). Wider columns as they are required in industrial plants can be made critically safe by incorporating a solid neutron absorber into the structure. A technical solution is, for instance, an annular column with its central tube filled with a neutron poison such as boron carbide. Even more efficient is a design where the sieve plates themselves are made from a corrosion-resistant neutron absorber material, such as hafnium [298].

It is not sufficient to make a single piece of equipment critically safe by its own; the possibility of neutron interaction between neighboring equipment, piping, etc. must be accounted for.

Nuclear Materials Safeguards. The International Atomic Energy Agency (IAEA) and the European Atomic Energy Community (Euratom) were established in 1957 in separate treaties. General aims were to foster and ensure the peaceful uses of atomic energy and to implement safeguards for this purpose. On 1st July 1968, the Treaty on the Non-Proliferation of Nuclear Weapons (NPT) was opened for signature. The IAEA began to develop an NPT-related safeguards system. With 43 ratifying states, the NPT entered into force on March 1970 for an initial period of 25 years. Practical basis for safeguards within the European Community are the Verification Agreement between IAEA and Euratom and its members [299], and the Euratom Regulation 3227/76 [300]. For each nuclear installation Particular Safeguards Provisions are issued.

International nuclear safeguards in general consist of four components: (1) containment, (2) surveillance, (3) accountancy, and (4) inspections. Depending on the type of nuclear facility, or part of it (material balance area, MBA), one or more components are necessary to detect the diversion of nuclear material. *Containment* and *surveillance* using seals and video cameras are typical instruments used in "item facilities" such as nuclear power stations or storage MBAs of reprocessing plants. Here identified and sometimes verified items (e.g., fuel elements) are fixed and observed in such a way that the continuity of knowledge is maintained. For the process area of "bulk handling facilities" (e.g., fuel fabrication, reprocessing) *accountancy* is mostly used. Relying on measurements and records, the operator declares the material balance within a period between two physical inventory takings. The inspectorates verify measurements by observation of operator actions or by independent methods (sample taking, analysis). Because of the great number of actions and data relevant to safeguards, bulk handling facilities need continuous inspections during operation times. Due to measurement uncertainties, differences can always be observed at physical inventory takings between booked and measured inventories. Differences between operator and inspector measurements also occur. The inspectorates evaluate these differences and decide whether they are statistically significant and therefore safeguards relevant. Depending on this decision further investigations might be necessary to fulfill the safeguards obligations.

For industrial-scale reprocessing plants containing higher amounts of "direct use material" (e.g., unirradiated plutonium), the internal IAEA rules lead to difficulties with the goal of timeliness of verification. Since the loss of 8 kg plutonium should be detected within one month, "classic" material balancing (process stop, clean-out, and verification of all nuclear materials) cannot be used. Therefore, an advanced method called " near-real-time accountancy" (NRTA) has been discussed and developed worldwide [301]. The basic idea is to establish short-time material balances from those measurement data on process inventories which are primarily collected for process control purposes. Then, sequential statistical tests are applied to the short-time material balances. The NRTA method is less intrusive to operation than "classic" inventory taking, however, much more information has to be processed and transmitted from the operator to the inspectorates.

5.4.2. Research and Development

Intense research and development work is or has been carried out in a number of countries, with emphasis on two targets. The more immediate of these is the optimization of existing LWR fuel reprocessing technologies, with a specific view on process economy and safety.

There is not a conflict between these aspects; instead, the extremely high safety standards posed in the nuclear industry normally have the effect that safety-related improvements produce economic benefits at the same time, and vice versa. The other target, which is directed more into the future, is the development and qualification of technologies for FBR fuel recycle.

5.4.2.1. Developments in LWR Fuel Reprocessing

A major economic burden in fuel reprocessing is the high cost of radioactive waste treatment, storage, and disposal. Efforts have therefore been made to minimize the production of radioactive waste streams. While it is obviously not possible to decrease the amount of radioactive nuclides to be handled, the possibility exists to decrease the mass and volume of inactive materials which are contaminated by radioactivity. In the chemical separation process, this refers particularly to the liquid medium- and low-activity waste streams, which contain only small amounts of radioactive material but often carry large amounts of dissolved, nonvolatile matter in the form of process reagents and reaction products.

Procedures have therefore been developed in which these nonvolatile reagents are either replaced by electrochemical redox processes, or by compounds such as hydrazine or hydroxylamine which are easily decomposed into gaseous products. Examples for such procedures which are sometimes termed "salt-free", are the plutonium – uranium partitioning by reductants such as uranium (IV) nitrate, hydroxylammonium nitrate, or electro-reduction, and the solvent cleanup by a hydrazine – carbon dioxide solution (see Sections 5.4.1.7, 5.4.1.8, 5.4.1.9). The medium-active waste streams which remain after electrochemical or chemical decomposition of the nitrogen-base reagents are essentially salt-free and can be evaporated down to small volumes. The treatment of these MAW concentrates can be further simplified by routing them into the HAW evaporator and thus combining them with the high-activity waste concentrate, without significant increase of the volume and solids content of the latter.

Another heavy burden on process economy is the requirement of remote operation in heavily shielded building structures equipped with a sophisticated and expensive infrastructure. Any process simplification which decreases the hot-cell space requirement is therefore a step towards lower process cost.

In the chemical separation process, the need for three successive extraction cycles for adequate purification of each product element is a complication which consumes ample hot-cell space. Consequently, efforts have been underway for many years to improve the efficiency of PUREX extraction so that the number of extraction cycles can be decreased. The ultimate outcome is the so- called IMPUREX (IMproved PUREX) process in which one single cycle of TBP solvent extraction combined with a compact nonextractive product refinement is sufficient for efficient purification [302].

The elements of IMPUREX, i.e., the process stages where essential improvements had to be effected, are summarized in Table 62. Core of the process is a PUREX extraction cycle where the solvent is loaded with heavy metals to nearly 100 % in the extraction – scrub section. As discussed earlier, this results in a very high fission product decontamination, but involves the risk of product losses in case of even slight deviations from the specified flowsheet. Two measures were taken to counteract this risk: (1) the uranium extraction front, which in IMPUREX is kept near to the HAW outlet, must be monitored and kept in position by an automatic control system regulating the extractant or feed flow; and (2) conditions had to be found where, in contrast to normal PUREX conditions, plutonium is better extracted than uranium, so that the less valuable product (uranium) instead of the more valuable plutonium would be lost to the HAW in case of a maloperation. Condition (1) could be fulfilled by continuous in-line temperature monitoring for the localization of the extraction front, i.e., by measuring the (exothermic) heat of extraction of uranium. For condition (2), extrapolations of the available data base [265] using the VISCO computer model [303] had indicated that the plutonium (IV) distribution coefficients might exceed those for uranium(VI) at increased temperature and nitric acid concentration, which was then experimentally confirmed (Fig. 129). However, for hexavalent plutonium $D(Pu^{VI})$ is smaller than $D(U^{VI})$ under all conditions, and consequently a pre-reduction

of Pu^{VI} in the feed solution is necessary to avoid plutonium losses. Of great importance is a highly efficient feed clarification, and in the laboratory-scale demonstrations discussed below, a fine-pore sinter metal filter followed by a bed of diatomaceous earth was effective. However, secondary waste is produced by this process, and consequently other possibilities such as an ultra-high-speed centrifuge should be investigated. Uranium – plutonium partitioning is performed using two electro-reduction columns in series instead of a single unit, resulting in a uranium product highly decontaminated from plutonium [304].

Table 62. Elements of IMPUREX

Measure	Purpose	Procedure
Feed clarification	avoid interfacial crud and minimize solvent degradation	sintered metal filter diatomaceous earth filter bed
"100 %" Solvent loading	high decontamination vs. yield	auto- control U extraction front
Feed prereduction	avoid Pu(VI) losses	e.g., electrochemically
Distribution coefficient $D_{Pu} > D_U$	avoid Pu(IV) accumulations	increased acidity and/or elevated temperature
Optimal extraction cycle	increase decontamination	optimize HA/HS 1/HS 2 length; adjust scrub flow ratios
Advanced U – Pu split	improve Pu-decontamination	two serial electroreduction columns
Additional product refinement	moderate maloperations backup	crystallization
N_2H_5OH/CO_2 solvent wash	medium active waste minimization	oxidation → N_2 + evap. → high active waste

Figure 129. Ratio of distribution coefficients for Pu(IV) and U(VI) as a function of nitric acid concentration and temperature, extractant = 30 vol % TBP – *n*-alkane [298]

A first "hot" demonstration of the one-cycle process was performed in the highly shielded, laboratory-scale extraction facility known as MILLI (because its throughput is 1 kg, or a milliton, of irradiated fuel per day) at the Institut für Heisse Chemie, Karlsruhe, Germany, using a fast-breeder MOX fuel of ca. 12 % Pu content, 110 000 MW · d/t average burnup, and 15 months cooling time which originated from the KNK II power station [305]. Extraction in the A mixer – settler was performed at an aqueous HNO_3 concentration of 4.9 mol/L and at 56 °C, with an organic solvent loading of ca. 93 % at the feed stage. Based on the VISCO model, the position of the extraction front which was monitored by temperature measurement as described above, was used as the reference variable for control of the solvent flow rate. Uranium losses to the HAW were restricted to 100 mg/L (corresponding to 0.1 %) while the plutonium losses, mainly caused by Pu^{VI} traces, were 10 mg/L (0.2 %). The feed filter system worked extremely well; no signs of crud formation could be seen, and despite the higher temperature and acidity, less dibutyl phosphoric acid than in former standard PUREX campains was formed. Fission product decontamination of the purified products was very satisfactory and for most impurities specifications were met. Table 63 summarizes the results of this experiment, and of a second campain in which LWR fuel irradiated to 31 500 MW · d/t burnup in the Swiss Goesgen power station was processed [305]. Final purification of uranium by the crystallization process described below yielded additional decontamination factors of > 100 for the most important fission products.

Freeze crystallization of uranyl nitrate hexahydrate (UNH) was developed as a compact uranium product refinement procedure [306]. The IMPUREX product solution is concentrated by evaporation to 300 – 700 g uranium per liter and adjusted to 4 – 6 mol HNO_3 per liter. Uranyl nitrate hexahydrate is crystallized by lowering the temperature to − 20 to − 30 °C at a rate of 1 to 3 °C/min. The high decontamination achieved for most impurities is based on the unique structure of the UO_2^{2+} cation and, hence, of the $UO_2(NO_3)_2 \cdot 6\,H_2O$ lattice which has no tendency to accept "normal" metal cations. Penta- or hexavalent neptunium and plutonium which would cocrystallize with the uranyl nitrate, are

Table 63. Fission product decontamination factors for uranium attained in the MILLI first cycle for two IMPUREX campains (FBR, LWR) as compared with a conventional PUREX campain (FBR), and with the DF required for 7 years cooled LWR fuel [305]

Fission Product	Approximate requirement for LWR	Conventional PUREX FBR	IMPUREX LWR (1990)	IMPUREX FBR (1988)
^{137}Cs	1×10^6	1.7×10^4	$7.4\times10^5-9.6\times10^7$	$5\times10^5-1.3\times10^6$
^{144}Ce	1×10^6	6×10^4	$1.7\times10^6-5\times10^8$	$1.5\times10^6-4.5\times10^6$
^{106}Ru	1×10^4	1.7×10^2	$3\times10^5-2\times10^6$	$1\times10^5-3\times10^5$
^{95}Zr	1×10^4	6×10^2	$5\times10^4-8\times10^5$	$1\times10^4-1.5\times10^4$
^{99}Tc	1.7×10^3		$>2\times10^4$	5×10^2

rejected after prior reduction to lower valency states. The mother liquor and wash solutions which contain up to 10 % of the uranium are recycled into the solvent extraction feed stage to recover the uranium together with residual plutonium, while the fission products report into the HAW; in this way, uranyl nitrate crystallization is an ideal "no-waste" process.

5.4.2.2. Reprocessing of Fast Breeder Reactor Fuels

The fuel for the sodium-cooled oxide-fuelled FBR is $(U, Pu)O_2$, a material similar to the UO_2 and MOX fuels used in LWRs. Indeed there are many more analogies in the reprocessing requirements for FBRs and LWRs, and it is therefore not surprising that most efforts for elaborating the technology for FBR fuel recycle have concentrated on the successful PUREX process. However, the technical requirements are distinctly more stringent in the FBR case, primarily due to the following reasons:

1) The concentration and radioactivity level of fission products in FBR fuel is higher at the time of reprocessing (Table 64) because the fuel burnup is higher, the cooling time is shorter, and the fission nuclide yield distribution is different. As Table 64 shows, the problem is somewhat eased if the axial blanket is coprocessed with the core fuel; it is further eased if the radial blanket is also coprocessed. The higher radiation level, and the associated higher thermal power have consequences on fuel transport and storage, on the layout of buildings and equipment, and on the radiation dose received by process reagents. It also requires a higher fission product decontamination factor if the same product specifications are applied as in the LWR case. A special problem is that part of the noble metal fission products remain undissolved as an insoluble, highly radioactive residue in the dissolver (ε-phase, see Section 5.4.1.4).
2) The plutonium concentration in FBR fuel is higher, but again the problem is eased if blanket material is coprocessed with the core fuel (Table 64). This has consequences on the criticality layout, and makes adaptations of the PUREX flowsheet necessary. In the dissolver the lower dissolution rate of MOX must be taken into account, and the fabrication of a highly homogeneous MOX is obligatory for proper fuel dissolution (see Section 5.4.1.4).
3) The use of sodium as the FBR reactor coolant influences fuel element transport and storage as well as the head-end treatment in the reprocessing plant because residues of sodium must be deactivated before the fuel element can be exposed to air, water, or nitric acid.
4) The design of FBR fuel elements is characterized by a very close package of thin fuel pin "needles" which are held in position by grid or spiral wire spacers, and by a mechanically stable stainless steel wrapper which holds this pin bundle arrangement together. This has specific consequences on the mechanical head-end treatment.
5) The use of stainless steel instead of Zircaloy as the cladding and structural material in FBR fuel elements is of relatively little influence on reprocessing. A specific chemical effect is that tritium is not chemically bound in stainless steel but instead diffuses through this material in the reactor, so that only a fraction of the tritium generated will still be present in the fuel at the time of reprocessing.

Modifications of existing technologies which have so far been elaborated are shortly reviewed

Table 64. Order-of-magnitude fuel data at the time of reprocessing for FBR and LWR

Parameter	FBR			LWR
	Core only	Core + axial blanket	Core + total blanket	
Average burnup, MW · d/t	75 000	45 000	35 000	35 000
Cooling time, a	1	1	1	5
Average Pu concentration, % of total heavy metals	15	10	7	1
Average fission product concentration, kg/t	77	46	36	36
Average fission product radioactivity, Bq/t	1.5×10^{17}	9×10^{16}	7×10^{16}	2×10^{16}

below. However, FBR reprocessing is not yet an industrially established process and still in the state of research and development.

Fuel Element Storage and Transport. Spent FBR fuel elements are discharged from the reactor into a sodium cooling pond which is usually integrated into the reactor. Due to the short cooling time and consequent higher thermal power output, transport to the reprocessing plant is best made using liquid sodium as the heat transfer medium.

Head-End Treatment. Sodium adhering to the fuel element after unloading from the transport flask must be deactivated by a water vapor – nitrogen treatment before the shear – leach process can be carried out. The stainless steel wrapper makes shearing of the entire FBR fuel element unadvisable and previous mechanical dismantling is preferred. The wrapper can be cut open either by a mechanical tool such as a saw, or by laser cutting. After removal of the wrapper the fuel pin bundle is sheared into segments of ca. 3 cm length which fall down into the dissolver. The dissolution rate is slower, and the amount of insoluble solid radioactive residues, notably the metallic ε-phase, is higher than in the LWR case.

Feed Pretreatment. Procedures used for iodine removal and clarification of the dissolver product are similar to those applied in LWR fuel reprocessing. Due to the high radioactivity of insoluble fines, with $^{95}Zr - ^{95}Nb$ still present, a highly efficient feed clarification is particularly important to avoid difficulties in the extraction process. Adjustment of the plutonium valency to +4, e.g., by careful electrochemical reduction of Pu (VI) and re-adjustment with NO_2, is advisable for the prevention of plutonium losses.

PUREX Process. Flowsheets for separating plutonium and uranium by the conventional three-cycle PUREX process have been elaborated and successfully tested on the laboratory and pilot plant scale. Measures which suppress the formation of dibutyl phosphate cruds, such as a high solvent loading and a high acidity in the extraction-scrub contactors, are of particular importance. For U – Pu partitioning salt-free processes are highly recommended. The British Dounreay Fast Reactor Reprocessing Pilot Plant which processes fuel from the 250 MW_e Prototype Fast Reactor, uses sulfuric acid as a nonreductive complexant for U – Pu partitioning [307]. The choice of highly corrosive sulfuric acid was dictated by capacity considerations when the original, much smaller facility was redesigned and scaled up to PFR throughput, and it is unlikely that this reagent will be applied in a commercial-scale plant.

The one-cycle IMPUREX concept (see Section 5.4.2.1) [305] is especially suitable for reprocessing of FBR fuel.

Other variations of the standard PUREX scheme include the replacement of TBP by trialkyl phosphate esters which show less tendency to form a third phase with plutonium (IV) (see Section 5.4.1.6). Promising results have for instance been reported for tri-isoamyl and tri-isohexyl phosphate extractants [308].

Status of FBR Fuel Reprocessing. In the most advanced countries the scale of FBR fuel reprocessing has reached the pilot-plant level. Thus, in France, the Atelier Pilot de Marcoule is used for pilot-scale demonstrations, and from 1977 to 1983 ca. 9 t of fuel from the 250 MW_e Phénix reactor containing 1.3 t plutonium have been treated. The plant was then refurbished

and extended, and is now available for demonstrations with both Phénix and Superphénix (1200 MW_e) fuel elements [309]. In addition several tonnes of Phénix fuel were coprocessed in mixtures with low-burnup, low-plutonium gas-graphite reactor fuel in the UP-2 plant at Cap de la Hague, demonstrating a way how FBR fuel could be economically processed in a period when FBRs are being introduced into an existing array of thermal power reactors, and when special FBR reprocessing plants are not yet existing.

The British Dounreay pilot plant which is operated in connection with the 250 MW_e Prototype Fast Reactor has already been mentioned [307]. In Japan, a pilot-scale FBR reprocessing plant which will be operated in conjunction with the 280 MW_e MONJU FBR is in the planning stage; its design is based on experience with a laboratory-scale facility at Tokay Mura. Other countries, such as the former Soviet Union [308] and Germany [305], have reported the reprocessing of FBR fuels on the laboratory scale.

Other Processes. A very different FBR reactor and fuel cycle concept is presently under investigation in the United States. The so-called Integral Fast Reactor (IFR) concept involves a pool-type, sodium-cooled reactor using a metal fuel, i.e., a 19 wt % U – 10 wt % Pu – Zr alloy, and a pyrometallurgical procedure for reprocessing and recycle of the fuel and blanket. The objectives of the IFR process are adequate (not necessarily high) removal of fission products, replacement of the plutonium consumed by fission with fresh plutonium generated in the blanket, and a > 98 % recovery of uranium and plutonium.

If successfully developed, the IFR process which is investigated at the Argonne National Laboratory, is planned to be tested on the pilot plant scale in the former EBR II Fuel Cycle Facility at Idaho Falls, Idaho. Modification of this facility which is still existent for IFR fuel cycle demonstrations is in the design stage [311].

The process which is investigated for the treatment of the core fuel is *high-temperature electrorefining* [310]. The fuel element is mechanically disassembled, and the pins are chopped into segments of ca. 6 mm length which are charged in an anode basket into the low-carbon steel electrorefiner vessel. The metal alloy fuel is leached out of the cladding hulls at 450 – 500 °C by liquid cadmium which becomes the anode of the cell. Uranium and plutonium are electrolytically transported through a molten salt electrolyte overlying the cadmium phase, and are deposited at a suitable cathode, e.g., cadmium contained in a ceramic crucible. The salt electrolyte is composed of stable chlorides, i.e., 35.5 mol % $BaCl_2$, 19.5 mol % $CaCl_2$, 37.0 mol % LiCl, and 8.0 mol % NaCl. Fission products are removed in three streams: (1) *gaseous fission products* are released during chopping and dissolution; (2) the *electrolyte salt* which contains electropositive fission products such as alkali, alkaline-earth, and rare earth metals; and (3) the *cadmium anode melt* which contains the noble metals fission products. For the separation of the purified U – Pu product from the cadmium cathode, vaporization of the cadmium is envisaged. For the processing of blanket material, a *halide slagging process* has been devised. The blanket alloy is molten at 1250 – 1300 °C in a beryllium oxide crucible which is not attacked by uranium, and the plutonium is preferentially extracted as $PuCl_3$ into an overlying $BaCl_2$– $CaCl_2$ salt melt which contains UCl_3 as the oxidant for plutonium. The salt extract in which the Pu: U ratio is much higher than in the original blanket alloy, is added to the electrolyte of the core electrorefiner to effect reenrichment of the core material with plutonium.

5.5. Radioactive Waste Management

5.5.1. Classification of Radioactive Waste

5.5.1.1. Generic Classification

Classifications of radioactive waste have often been proposed [312–316], but no generic, universally applicable, and quantitative classification exists for raw waste or for conditioned waste packages. A multitude of subdivisions for radioactive waste has been proposed or applied. Most commonly, a classification according to low active waste (LAW), medium active waste (MAW), and high active waste (HAW) is utilized. This subdivision is useful in handling and treating radioactive waste of a known type and radionuclide composition. Definitions of these classes differ greatly. Activity concentrations,

dose rates, and content of α emitters have, for example, been used as parameters for classification along with definitions according to the origin or type of waste.

Simple classifications according to LAW, MAW, and HAW do not allow a safety-related judgement of waste. They do not include sufficient information to draw conclusions for the release of radionuclides and the dose to humans under normal or extraordinary conditions (defined in the assumed scenarios of safety assessments). The resulting radiation exposure in a given scenario can be higher from a poorly conditioned waste with low activity than from an excellently conditioned high-activity waste. To comply with the requirements for radioactive waste, the simple definitions of LAW, MAW, and HAW must be abandoned and a more informative system of waste description established.

5.5.1.2. Waste Classification for Disposal

The system of waste classification is best developed from a disposal point of view because a repository must handle all types of waste from various waste producers and cannot be tailored to an individual waste source.

Radioactive waste can be divided into *heat-generating waste* and *non-heat-generating waste* [316], because the thermomechanical effects that result from heating the host rock necessitate very specific, additional investigations, layouts, and proofs. Non-heat-generating waste can additionally be subdivided into so called α *waste* and *non-α waste*. This subdivision is important if non-α waste with short-lived radionuclides is intended to be disposed of in shallow ground. Waste with long-lived α-emitting radionuclides must be disposed of in deep geological formations.

For further characterization, various radioactive waste must be categorized [317], [318] and their properties described individually in data sheets that include sufficient information to plan the installation and to perform safety assessments.

As a consequence of site-specific safety assessments, the various waste categories can be condensed into a few, well-defined classes with similar behavior for release of radionuclides. This has been demonstrated for the Konrad repository [319]. As a result, six *waste form groups* and two *waste packaging classes* [319], [320] were defined.

5.5.1.3. Catalog of Waste Types

The definition of waste form groups and waste packaging classes is the starting point for the development of a waste type catalog because different radioactive wastes must be adequately separated to allow appropriate pretreatment and conditioning for interim storage and disposal. The waste type catalog surveys radioactive waste from its generation in a nuclear facility until its disposal in a repository [321], [322]. This catalog specifies the raw waste, pretreatment methods, and resulting intermediate products, as well as the conditioning methods and waste packages required. It thus describes the "flow" of radioactive waste.

The subdivision of *raw waste* is hierarchically organized into *waste groups*, *waste subgroups*, and *waste types*. The assignment of raw waste to a waste group, waste subgroup, or waste type must be performed in accordance with the requirements of waste pretreatment and the conditioning process. If necessary, raw waste must be sorted or specified in more detail, for example, if it is categorized as chemicals, filters, or metals. Raw waste can be *pretreated* to form an *intermediate product* and must be *conditioned* (treatment and packing) to a *waste package* (waste form and packaging).

This waste type catalog, therefore, forms the basis for the description and separation of radioactive waste from the raw waste into a waste package suitable for disposal. It guarantees the necessary clarity in waste management, gives guidance for waste conditioning, allows determination of relevant data for classified wastes, and ensures sufficient supervision of various waste management steps by the authorities.

5.5.2. Conditioning of Radioactive Waste

5.5.2.1. Heat-Generating Radioactive Waste

Heat-generating radioactive waste contains such a high concentration of radionuclides that heat is emitted which necessitates cooling. This waste

includes spent fuel elements (if these are deemed to be a waste), high-level liquid waste and dissolution residues such as hulls and ends from spent fuel reprocessing, and highly activated core components from reactors.

High-Level Liquid Waste. High-level liquid waste results from the reprocessing of spent fuel and represents fission product concentrates that contain about 300 g/L of element nitrates in nitric acid solution. These liquids are stored in cooled stainless steel tanks. The storage time is kept short (e.g., one year), if a conditioning process and an interim storage facility or a repository are available.

Various conditioning concepts have been discussed and investigated. Examples are vitrification in borosilicate and phosphate glasses [323], [324]; embedding in ceramic materials (e.g., Synroc, [325]); and production of an advanced calcination product (e.g., Supercalcine). At present virtrification in borosilicate glasses is the primary choice for solidification of high-level liquid wastes. The following are the principal process steps involved: (1) concentration, (2) denitration, (3) drying, (4) calcination, (5) melting with glass frit, and (6) pouring the melt into a stainless steel canister. The off-gas of a vitrification process passes through an off-gas cleaning system before it is discharged.

Two virtrification processes have been applied in longer, active operation: the AVM and the Pamela processes.

A VM process (Atelier de Virtrification Marcoule, France). The main pieces of equipment in this process are a rotary kiln calciner and a metallic melter [323]. The high-level liquid waste is mixed with sugar as a denitration agent and then fed into the *calciner* where it is denitrated, dried, and calcinated. The calcine, the dissolution fines, and the glass frit are fed into the *melter*, which is operated at ca. 1100 °C. The radioactive waste is dissolved and the fines are embedded in the glass which is poured batchwise through a bottom drain into the canister. The glass solidifies on cooling. Based on experience with the AVM process since June 1978, a vitrification plant has been built to immobilize high-level liquid waste from the reprocessing plant at La Hague, France. The first hot glass block was cast in June 1989.

Pamela Process (acronym for: Pilot-Anlage zur Erzeugung lagerfähiger Abfälle, Belgium). The primary component of this process [324] is an electric, direct-heated ceramic melter. A mixture of liquid waste, glass, and additives is fed directly into the melter. This feed forms a layer of solid product on top of the melt, which reduces the release of volatile radionuclides such as ruthenium. All steps in glass fabrication–denitration, drying, calcination, and melting–are carried out inside the melter. The glass is drained off either through a bottom outlet or via a continuous overflow.

The Pamela facility, run in German – Belgian cooperation, started operation in 1985 and will have solidified high-level liquid waste stored at the Eurochemic reprocessing plant in 1991. After that, the Pamela plant might be used to vitrify high-level liquid waste from the reprocessing plant at Karlsruhe (WAK), if the transport of the liquid HAW is accepted.

Dissolution Residues and Reactor Core Components. The spent fuel elements are chopped up, and the fuel is dissolved in nitric acid solution in a reprocessing plant. Hulls, end pieces, and insoluble fines remain as residue. These require a conditioning technique that yields a product with sufficient radiation and temperature resistance. Cementation has been applied [326], and high-pressure compaction, resulting in the fabrication of pellets, is in the developmental stage [327].

Reactor core components are packed primarily into high-integrity packages without fixation [328].

Spent Fuel. If spent fuel is disposed of as radioactive waste it has to be conditioned in such a way that the volatile radionuclides in the fuel pins are retained in the waste package or released during conditioning.

One possibility is packing of spent fuel elements (or fuel pins after disassembling) into a thick-walled, gastight, self-shielded, high-integrity package that can be stored and/or disposed of [329]. Packaging made of cast iron, steel, copper, or lead has been developed. It can have an overall mass up to 120 t if used for transportation and storage. The weight of waste packages used for the disposal of spent fuel in deep

geological formations is currently limited to 65 t because of the capacity of the hoist cage.

An alternative is packaging cut fuel pins in a steel canister that has the same dimensions as the canister for glass blocks from virtrification of high-level liquid waste [330]. In this case, identical techniques for storage, transportation, and disposal of spent fuel and glass blocks can be used.

Interim Storage of Immobilized Heat-Generating Radioactive Waste. Heat-generating radioactive waste must be stored in such a way that the heat is removed. In principle, air or water cooling can be used, but air cooling is preferred at present. Several technical solutions are possible and the following concepts have been selected:

1) Thick-walled, cast-iron packages of heat-generating radioactive waste, especially spent fuel, are stored in a concrete building with inlets for cooling air in the side walls and outlets in the roof [331]. The packaging is the barrier against radionuclide release, therefore, the building is not considered as protection in safety assessments. Such a facility has been built at Gorleben, Germany. The licensed facility has not yet been taken into operation.
2) An air-cooled store for high-level glass blocks is operated in Marcoule, France [323]. The glass blocks are emplaced with a loading machine in vertical shafts that are cooled by a heat-induced natural air draft supported by the exhaust stack. The storage shafts are plugged, and thus the area on top of the shafts is accessible. The building has no protection against outside factors such as an airplane crash. A similar facility is in operation at La Hague, France.

5.5.2.2. Non-Heat-Generating Radioactive Waste

Minimization and Avoidance of Radioactive Waste. The minimization of radioactive waste is especially important for non-heat-generating waste. This waste consists mainly of inactive materials that are contaminated or activated and contain only small amounts of radioactive isotopes.

In principle, all materials that are introduced into a radioactive process or into a radioactive control area could be released as radioactive waste. Systematic, intelligent process and plant design is of utmost importance for the reduction of waste which can be achieved by:

1) Electrolytic techniques [332];
2) Chemicals that react to form nontoxic gaseous compounds or that can be decomposed by electrolysis or by thermal treatment [332], [333];
3) Use of heterogeneous instead of homogeneous neutron poisons [334];
4) Use of effective decontamination methods with a minimum of waste and re-use of decontaminated materials [333]; and
5) Decay of short-lived radioactivity and disposal as nonradioactive waste.

The minimization of radioactive waste through the avoidance of waste in combination with volume-reducing waste conditioning techniques has already been successfully applied. This results in continuously declining amounts of conditioned radioactive wastes.

Conditioning Techniques. Conditioning of radioactive waste includes processing and packaging of the waste, if required, after pretreatment or sorting. Various techniques and strategies are applied. The selection of a conditioning process depends on factors such as the requirements for storage and disposal; the overall costs of conditioning, storage, and disposal; acceptance of the process; and the volume of the resulting waste packages. Therefore, waste producers in different countries may apply different conditioning techniques to the same type of waste. Furthermore, the need to minimize the volume of conditioned waste, because of repository shortage, stimulates the development of new conditioning techniques.

Pretreatment of Radioactive Waste. Raw waste must be collected and pretreated in such a way that it becomes suitable for the conditioning process. Pretreatment methods include decontamination, crushing, compression, evaporation – distillation – rectification, decantation – dewatering – filtration, and incineration – pyrolysis [321], [322], [333], [335], [336].

Incineration is especially attractive for all types of combustible waste. Solid or liquid waste including alpha contaminated waste are incinerated. The large volume reduction and the inorganic and inert character of the intermediate products (e.g., ash or slag) favor the incineration process [321]. However, off-gas treatment and secondary waste must be taken into account.

Treatment of Radioactive Waste. The *cementation* of radioactive waste is widely applied [333], [335]. It is used for (1) the solidification of liquids; (2) the embedding of solids such as ash, powder, and granules; and (3) the casting of voids in scrap, rubble, or filters. Various cementation techniques are used, and the equipment can be mobile or stationary.

Liquid radioactive waste is mixed with dry cement. This mixing is carried out by continuous mixers, batchwise in-drum mixing, tumbling, or with "lost" stirring blades (i.e., blades that remain in the waste after cementation).

The liquid radioactive waste reacts with the cement and is bound in the product. The compatibility of the cement and the liquid radioactive waste must be checked to guarantee that the product sets. If necessary, special cement formulations are developed or suitable additives are used.

Solid radioactive waste such as drying residue from liquids, ash from the incineration of combustible radioactive waste, or granulated material such as silica gel or ion exchange resins is often embedded in cement by mixing techniques. Reactions with the cement must be taken into account, e.g., reactions with amphoteric metals in the ash under evolution of gas or swelling of dried resins.

Casting of void spaces between solid materials is used to fill the space between wastes, to contain possible surface contamination or residual liquid, and to hinder radionuclide release.

Cementation technology is relatively simple and is widely applied. However, more advanced processes are becoming very attractive because of volume minimization.

Bituminization is a classic process for the solidification of liquid radioactive waste [335]. The liquid and the bitumen are mixed at $\geq 150\,^{\circ}\mathrm{C}$ in an extruder, a film, or a mixer – evaporator. The solids contained in the liquid are incorporated into the bitumen, which cools down after it is poured into packaging. The bituminization process must be carefully planned to avoid, e.g., exothermic reactions or self-ignition of the hot bitumen product. The product must be protected in a suitable packaging or building to avoid unacceptable radionuclide releases, e.g., as a consequence of a fire. Furthermore, the tendency toward swelling due to radiolytic gas generation must be taken into consideration. These facts hamper the application of bituminization.

Polymers are used in only a few cases [336], [337]. The embedding of resins with polystyrene is one example. The solidification of tributyl phosphate in poly(vinyl chloride) is being investigated. In general, the monomers are combined with the radioactive waste. Mixing techniques are comparable to those used in bituminization. Polymerization is initiated by a catalyst or by radiation.

High-pressure compaction with 1500 – 2000-t compactors is a new development for minimizing waste amounts [328]. Solid material in a drum is compacted to a form-stable pellet. This technique is used with metallic materials, paper, plastic and clothes, rubble, and even ash from the incineration of organic radioactive waste. In 1988, unexpected gas generation was detected in compacted waste. Investigation showed that corrosion occurred when the metal came in contact with wet organic materials. This experience demonstrates that waste must either be dry or sorted before compaction.

Drying of liquid radioactive waste is a new development for waste minimization [328]. The liquid is fed into a packaging that is heated. Evaporation is supported by application of a slight vacuum. The resulting dry residue consists of the inactive and active constituents that were dissolved or dispersed in the liquid. The activity concentration in the resulting product is thus higher than in the cemented waste form; therefore, superior shielding (often made of cast iron) is required.

Melting of metallic radioactive materials (e.g., after decontamination) is of special interest for the decommissioning, repair, and maintenance of nuclear facilities. If the radioactivity level in the melt is low the metals can be reused in casting packagings for radioactive waste disposal. If the radionuclide content is too high the melt must be poured into packaging as radioac-

tive waste. The resulting slag also has to be conditioned and disposed of.

Packaging of Radioactive Waste. Radioactive waste must be packaged for handling and transportation. Packagings for disposal may be designed for the following functions:

shielding of the radiation,
retention of volatile radionuclides,
protection against undesired events (e.g., fire or dropping of a waste package), and
acting as a barrier to radionuclide release after an ingress of water.

The necessary quality of a packaging depends on the type of waste and its radionuclide inventory. Packaging requirements can be fulfilled by the packaging alone or by a shipping cask. Sheet steel, reinforced concrete, and cast iron are common packaging materials. Cylindrical and rectangular packagings of different size and weight are being used. Standardization of packaging is necessary to make the equipment, as well as the handling and disposal techniques, compatible [320].

The conditioning of radioactive waste by packaging only is also employed, primarily with superior packaging (e.g., cast iron). This packaging is employed for activated materials and ion-exchange resins that have higher radionuclide inventories [328].

5.5.3. Origin and Amount of Radioactive Waste

A realistic data base is an essential prerequisite for the development of disposal strategies or the planning and construction of repositories. Data on the origin, type, and expected amount of radioactive waste are therefore necessary to estimate the required disposal capacity.

5.5.3.1. Origin of Radioactive Waste

Radioactive waste basically originates from:

1) The operation of light-water reactors and reactors of advanced design (breeder reactors and pebble bed reactors);
2) The reprocessing of spent fuel elements from nuclear power plants;
3) Basic and applied investigations at nuclear research centers;
4) Other research centers, universities, industries, or medical applications of radioisotopes;
5) Uranium enrichment and the production of fuel elements, and industrial research and development;
6) Decommissioning and dismantling of nuclear facilities; and
7) Other waste producers, e.g., the pharmaceutical industry or the army.

In addition, spent fuel elements from light-water reactors and pebble bed reactors must also be considered.

5.5.3.2. Present Amount of Unconditioned and Conditioned Radioactive Waste

The origin and amount of radioactive waste in Germany [338] are representative for a country having a well-developed nuclear technology. Thus, they may be used to provide information on the amount of radioactive waste arisings.

On behalf of the Bundesminister für Umwelt, Naturschutz und Reaktorsicherheit (BMU, i.e., Federal Minister for Environment, Nature Protection, and Nuclear Safety), the Physikalisch-Technische Bundesanstalt (PTB) has carried out annual inquiries concerning the amount of unconditioned and conditioned radioactive waste produced in Germany since 1985. [The responsibility for the long-term storage and disposal of radioactive waste was transferred from the PTB to the newly founded Bundesamt für Strahlenschutz (Bf S) on November 1, 1989.] According to the latest inquiry [339], the amount of unconditioned radioactive waste (primary waste volume) was about 13 000 m^3 on December 31, 1989 (including about 1300 m^3 of short-lived waste stored for decay). This was produced mainly by nuclear power plants (ca. 8100 m^3), collecting depots of the federal states (about 2400 m^3; radioactive waste originating from other research centers, universities, industries, or from medical application of radioisotopes is generally handed over to collecting depots), and the Karlsruhe and Jülich nuclear research centers (about 1200 m^3). The volume of conditioned (i.e., processed and packaged) radioactive waste amounted to about 44 400 m^3. Of this,

Table 65. Amount of unconditioned and conditioned radioactive waste in the Federal Republic of Germany (including short-lived waste stored for decay)

Origin	Primary waste, m^3	Conditioned waste, m^3		
	Amount stored up to Dec. 31, 1989	Amount stored up to Dec. 31, 1989	Amount produced from Jan. 1 to Dec. 31, 1989	Estimated amount in 1990
Reprocessing	148	8 955	615	615
Nuclear power plants	8 140	13 827	997	3 017
Collecting depots	2 384	1 699	101	79
Nuclear research centers	1 245	18 105	1 760	2 681
Nuclear fuel cycle industry	878	1 743	266	516
Other waste producers	236	91	8	8
Total	13 031	44 420	3 747	6 916

waste from the research centers contributed ca. 18 100 m^3; waste from the operation of nuclear power plants, ca. 13 800 m^3; and that from reprocessing spent fuel elements ca. 9000 m^3. Details on the origin and amount of unconditioned and conditioned radioactive waste are given in Table 65.

In comparison to the amount of radioactive waste occurring in other countries, the total waste package volume in Germany is rather small. It indicates the use of modern conditioning techniques (i.e., waste product minimization via high-pressure compaction, incineration, and thick-walled cast-iron packaging).

5.5.3.3. Future Amounts of Radioactive Waste

Based on annual surveys and data presented to the BfS by waste producers, future amounts of conditioned radioactive waste can be estimated up to the year 2000 [339]. Taking into account that the volume of arising radioactive waste was always lower than the amount calculated on the basis of model data from the waste producers, two forecasts with different data were made. The forecast on the basis of the model data is assumed to be an upper limit for the occurring waste, and the forecast on the basis of an extrapolation of the number of actually arising waste packages is assumed to be a lower limit for the amount of waste at the end of the year 2000. Thus, the prognosis is based on the following assumptions and boundary conditions: (1) the installation of nuclear power plants with a total electricity-generating capacity of about 24 GW by the year 2000; (2) the return of radioactive waste due to the reprocessing of spent fuel elements from nuclear power plants in Germany from 1993 onwards [reprocessing is carried out by Compagnie Générale des Matières Nucléaires (COGEMA) in France and British Nuclear Fuel plc (BNFL) in Great Britain], and (3) an annual amount of radioactive waste originating from nuclear research centers, the nuclear fuel cycle industry, the collecting depots, and from other waste producers which, based on current amounts, is considered to be constant.

The prognosis predicts an amount of radioactive waste with negligible heat generation at the end of the year 2000 (see Fig. 130) of about 170 900 m^3 (upper estimate) or of about 129 900 m^3 (lower estimate). Taking into account the overestimation of the expected amount of waste by the model data [339], it is interesting to see that the waste quantities estimated by the PTB on the basis of the inquiry for 1986 lie just in the middle of this bandwidth [340].

The distribution of the predicted amount of waste (upper estimate) between the various groups of waste producers at the end of the year 2000 shows the following results:

reprocessing	32.2 %
nuclear power plants	28.8 %
research centers	26.2 %
others	12.8 %

The amount of conditioned heat-generating radioactive waste at the end of the year 2000 is estimated to about 3600 m^3 (upper estimate) or to about 3200 m^3 (lower estimate).

Figure 130. Expected amounts (upper and lower estimates) of conditioned radioactive waste with negligible heat generation accumulated up to the year 2000

5.5.4. Disposal of Radioactive Waste

The overall objective of radioactive waste disposal is to ensure that waste is handled and stored in such a way that, at present and in the future, the protection of humans and the environment from harm caused by the ionizing radiation from these wastes is guaranteed [313], [341]. Effective protection can be achieved by adhering to the basic principles of radiation protection; proper planning; and the adoption of appropriate methods for the conditioning, handling, and disposal of radioactive waste. Important considerations for waste disposal are the selection of an appropriate disposal site with its specific confinement characteristics and the implementation of engineered barriers (e.g., immobilization of material, packaging, disposal room, and shaft sealing) so that radioactive waste is adequately isolated from the biosphere.

Wide international agreement exists that the multibarrier concept (i.e., imposing natural and engineered barriers between radioactive waste and the biosphere) is particularly advantageous and should be adopted in any waste disposal system. Thus, the release of radioactive material can be limited or delayed, its transport retarded, or its concentration sufficiently diluted to ensure that the impact on humans and the environment remains within acceptable limits.

5.5.4.1. Principles of Waste Disposal

Two basic waste management techniques exist that can be used to comply with the objective of disposal:

1) *Disposal to the environment* so that radioactive waste is diluted to a level that posess no harm to humans and the environment
2) *Containment of the waste*, to achieve the required degree of isolation from humans and the environment, until the radioactivity has decayed to insignificant levels

In practice, disposal to the environment has been realized by sea dumping and emplacement in the ocean floor; containment of the waste has been realized by shallow land burial and disposal in geological formations. The safety of sea dumping relies on the vast dilution of the radioactivity as it disperses at the bottom of the ocean. The quantities of activity dispersed by this method are very small compared with the natural activity of the oceans. *Sea dumping* of radioactive waste was successfully practiced under the auspices of the OECD Nuclear Energy Agency [342]. However, this operation was stopped in 1983, and it will probably not be resumed. The research and development program for *emplacing vitrified radioactive waste in the ocean floor*, coordinated by the OECD Nuclear Energy Agency, also suffered a severe setback

by the withdrawal of the United States from international cooperation.

With these techniques out of favor, the primary emphasis in radioactive waste disposal now rests with land-based facilities. The international view is that shorter-lived radionuclides, or waste containing rather low concentrations of long-lived radionuclides can, if appropriate, be *buried* near the surface. Long-lived radioactive waste requires a higher degree of isolation and should be disposed of predominantly in geological formations. Thus, shallow land burial in highly engineered facilities (i.e., near-surface repositories) or disposal in deep-lying repositories has generally been favored.

The objective of waste disposal applies to all types of radioactive waste. To demonstrate that this objective can be achieved, according to a wide measure of agreement, a safety assessment must be performed that takes into account the geological and hydrogeological situation, the technical design of the facility including its scheduled mode of operation, and the type of waste packages to be disposed of.

5.5.4.2. Underground Laboratories

An essential prerequisite for a safety assessment-oriented approach to disposal is the provision of a comprehensive, realistic data base. The necessary data must be provided by site-specific above-ground and underground investigation programs, by information on disposal-relevant characteristics of the waste packages, and by appropriate planning of the disposal facility.

A very important feature in the framework of research and development programs is the operation of underground laboratories. In these laboratories, in situ measurements and experiments can be carried out, and waste handling and emplacement techniques can be demonstrated. Thus, necessary data and experience can be obtained to aid the design of future repositories in geologic formations. Such installations are in operation in Switzerland, Sweden, and Germany.

Switzerland. At the Grimsel pass in the Swiss alps an underground rock laboratory has been established in granite. Since 1984, extensive research programs have been carried out at the Grimsel test site, including methods for nondestructive rock investigations, rock movement measurements, and various tests regarding rock mechanics and hydrogeologic measurements.

Sweden. At Stripa, an abandoned iron ore mine in central Sweden, an international project under the sponsorship of the OECD Nuclear Energy Agency is being conducted. The project is mainly concerned with investigation into the flow and chemistry of groundwater, the migration of radionuclides in granite, and the behavior of bentonite clay as a material for backfilling of cavities.

Germany. In Germany the former Asse salt mine near Remlingen/Wolfenbüttel has been used since 1965 to carry out comprehensive research and development programs. Within the scope of these programs, about 124 500 drums of low-level radioactive waste and about 1300 drums of intermediate-level waste had been disposed of by the end of 1978 [343]. Since then, research activities have continued without further storage. At present, the disposal of heat-generating waste is being investigated under international cooperation.

Information gathered in the different underground laboratories is exchanged so that it can be cross-checked. This information provides a valuable source of knowledge in further planning of deep-lying repositories.

5.5.4.3. Near-Surface Repositories

Short-lived radioactive waste can be sufficiently isolated from humans and the environment in engineered near-surface facilities. Shallow land burial is practiced on an industrial scale in Great Britain, Sweden, and especially, France.

Great Britain. Most of the low-level radioactive waste in Great Britain is disposed of at the Drigg site in Sellafield in Cumbria. The waste is disposed of in large trenches that are covered by soil and a waterproof layer. According to current planning, the disposal concept will be changed, and this type of waste will be disposed of in a deep-lying repository (200 – 1000-m depth) soon after the turn of the century [344].

Sweden. In Sweden the SFR repository is located 1 km offshore of the Forsmark nuclear power plant and consists of a series of caverns and silos ca. 60 m below the seabed. Access

to this repository is by road tunnels from land. The SFR repository is designed to hold about 90 000 m^3 of waste package. The first phase, which was completed in 1988 and has been in operation since then, includes one concrete-walled silo and four caverns. The remaining silos and caverns are scheduled for completion at the end of the century.

France. In France, short-lived radioactive waste is routinely disposed of in surface concrete facilities. The waste packages (concrete blocks consisting of steel drums in cylindrical concrete packaging or concrete boxes) are stacked in concrete trenches. The trenches are then backfilled with concrete and protected by waterproof covers against rainwater infiltration. Via a system of monitoring shafts, the state of this disposal facility can be checked, and any water that has infiltrated can be collected and treated. These techniques are used at the disposal site of La Manche, next to the La Hague reprocessing plant, where almost 400 000 m^3 of waste package has been disposed of since 1969. As the La Manche site is likely to be saturated at the beginning of the 1990s, a new site is being constructed at Soulaines, 200 km southeast of Paris. This 1 000 000-m^3 site is now in operation.

5.5.4.4. Underground Repositories

National programs and time scales for the planning and operation of deep-lying repositories vary widely because of the different economic, political, and technical circumstances, and the different boundary conditions to be considered in different countries. Important technical considerations are the type and volume of radioactive waste to be disposed of, the availability of disposal options, and the need for further research and development prior to detailed planning of repositories.

Many countries are still involved in the discussion of disposal concepts, the performance of research and development programs, and preliminary planning work for disposal facilities in geologic formations. However, progress has been made (e.g., in the United States and Germany).

United States. In the United States, a strict separation exists between radioactive waste originating from commercial applications and that originating from the defense program. The Waste Isolation Pilot Plant (WIPP), which has been constructed in a bedded salt formation near Carlsbad, New Mexico, is designed to receive transuranic radioactive waste from the U.S. defense program [342] [transuranic waste is material containing α- emitters in concentrations $> 3.7 \times 10^3$ Bq/g (> 100 nCi/g)]. A broad research and development program is also being carried out at WIPP.

Germany. In Germany, three sites are being considered for repositories:

The Abandoned Konrad Iron Ore Mine. Here, radioactive waste with negligible heat generation is to be disposed of, i.e., the host rock temperature must not be increased by more than 3 K on an average by the waste package [345].

The Konrad repository will be operated with two shafts. The sequence of strata in the coral oolite at a depth of 800 – 1300 m is available as emplacement formation. A repository cavity of about 1 000 000 m^3 will be excavated, allowing disposal of a waste package volume of ca. 650 000 m^3. At the end of a 40-year operational lifetime a total activity on the order of 10^{18} Bq is anticipated in this facility. The licensing procedure was started in August 1982. Operation of the Konrad repository is expected to begin in the mid-1990s.

Gorleben Salt Dome. The planned repository in the Gorleben salt dome is designed for the disposal of all kinds of solid and solidified radioactive waste, including the emplacement of heat-generating waste from reprocessing [330], [346]. According to plans the Gorleben repository will also operate with two shafts. The emplacement level is at a depth of about 870 m. The cumulative inventory of radioactive waste to be disposed of during an operational lifetime of nearly 70 years, is estimated to be on the order of 10^{21} Bq. At present, after comprehensive aboveground investigation, two exploratory shafts are being sunk. On completion of these shafts, the underground site investigation program will be initiated. The start of operation of the Gorleben repository is scheduled for the year 2008.

Morsleben Repository. In the former German Democratic Republic an abandoned salt mine in Morsleben near Helmstedt was selected

and reconstructed to serve as a repository for radioactive waste originating from the operation of nuclear power plants and from radioisotope production and application [347]. This facility began continuous operation in 1981. Liquid waste is solidified in situ in the disposal cavities by using lignite filter ash as the binder. Solid primary radioactive waste is disposed of in cavities without immobilization; 200-L drums of solid or solidified waste are stacked in disposal chambers.

After German unification in October 1990, a safety assessment on this repository is being performed on behalf of the BMU. The results of this assessment, among other things, will form a basis for decisions concerning the future use of the facility.

5.6. Safety Aspects in the Design of Reprocessing and Waste Treatment Plants

Legislation concerning the safety of reprocessing plants is similar worldwide. Thus safety requirements mandated by the German authorities are described in the following sections as an example. An overview of international legislation is given in Section 5.6.8.

5.6.1. Objectives of Protection

The construction and operation of a reprocessing plant, including facilities for waste treatment, require a permit according to § 7 of the German atomic law (Atomgesetz AtG) [348]. This permit can be granted only if in the design and operation of the plant, all precautions taken against damage represent the state of the art. According to the radiation protection decree (Strahlenschutzverordnung, StrlSchV) the technical design and operation must fulfill the following safety objectives [349]:

1) Any unnecessary exposure or contamination of persons, material goods, or the environment is to be avoided [349], (§ 28, Section 1, No. 1).
2) Any exposure or contamination of persons, material goods, or the environment– even if below stipulated limits–is to be kept as low as possible in terms of both the state of the art and all circumstances of the individual case ([349], § 28, Section 1, No. 2, § 44, § 45, § 49 – 56).
3) The planning of structural or other safety measures for design accidents, notwithstanding requirement (1), must be based at least on the malfunction planning values of § 28, Section 3 of the StrlSchV [349].

These stipulations result in the following basic *safety objectives*:

Enclosure, retention, and shielding of radioactive substances
Minimization and control of the discharge of radioactive substances via exhaust air and wastewater
Guarantee of nuclear subcriticality
Avoidance of fire and explosion or their effective control
Safe removal of radioactive decay heat or other waste heat
Protection against outside influences (plane crash, earthquake, chemical explosion, etc.)
Design compliance with all operational and maintenance requirements so as to avoid contamination and minimize the exposure of operating personnel to radiation
Provisions to be made with regard to closing and decommissioning of the plant

A comprehensive *safety concept* is necessary to fulfill these basic requirements. Important features of this safety concept are:

- Multishelled enclosure of radioactive substances (multiple barrier concept)
- Equipment with monitoring and safety facilities; redundancies for maintenance of important protective functions (i.e., more ready-to-use technical means must be available than are required to carry out scheduled functions)
- Redundancy of safety measures by using auxiliary devices that differ in type and mode of operation
- Safety-oriented quality-securing measures
- Precautions for safe operation, maintenance, and shutdown, safety in the case of malfunction, and reduction and elimination of the effects of malfunction
- Training of operating personnel and safety-oriented organization of the course of operations.

Additional requirements exist with regard to liability in case of damage [350], protection against action from third parties, and control of fissionable materials on the basis of international agreements [351].

5.6.2. Safety Through Multiple Barrier Enclosure

Safe operation and permanently effective enclosure of large amounts of radioactive material can be guaranteed by means of construction, control, and administrative measures [352]. Every future licensing procedure for a reprocessing plant must conform with safety criteria stipulated by the government. In nuclear technology, the multiple barrier principle is applied not only in nuclear power plants, but also in reprocessing plants and storage facilities for radioactive waste. Figure 131 shows the enclosure technology typical for a reprocessing plant. Chemical reactions occur in leaktight containers or apparatus that are interconnected by piping (*first barrier*). The process vessels and piping systems are enclosed in a hot cell, which is cladded with stainless steel to ensure that it is gastight. Radiation shielding is guaranteed by thick concrete walls (*second barrier*). The concrete cells are, in turn, located in a massive building, which takes over the function of the *third barrier* and is simultaneously designed as protection against outside influences.

Special attention must also be directed to the redundant protective effect of the barriers for all media piping employed in supply and removal. This is achieved by the use of double locks that are effective independently of each other, multiple filters, and quick shutting dampers. The rooms and hot cells are maintained at a stepwise decreasing subatmospheric pressure (lowest subatmospheric pressure inside the hot cells) to prevent the uncontrolled escape of radioactivity. Thus, air always flows from the outside into the process building, then into the cells, and finally either via the equipment or directly through a multiple filter system to the outlet air stack. Wastewater is passed first through storage tanks and purification facilitites, and only after careful examination is it allowed to enter the main drainage.

5.6.3. Safety Measures for Protection of Employees

The protection of employees against the dangers of radioactivity is guaranteed not only by closed, controlled, and monitored areas within the plant, but also by constant supervision with the help of personnel dosimetry and regular medical control. Exposure of operating personnel to radiation is always kept below permitted values by efficient shielding, by monitoring both the local dose rate and the personal dose, and by restricting accessibility to rooms with a higher level of radiation. Indeed, § 51 StrlSchV and § 44 StrlSchV must be adhered to at all times for internal and external supervisory areas, respectively. The local dose rate in places where maintenance work is carried out must be low enough that, given the frequency of maintenance, the exposure of personnel meets the demands of § 28 Section 1 StrlSchV [349], after all other contributions to exposure have been taken into account.

Remote-controlled systems or shielded rooms are provided for the removal, repair, and storage of contaminated components with a high local dose rate. Shielding measures, automation, or remote control is to be used for work involving unavoidably high local dose rates.

Special protective measures for personnel must be taken in the event of malfunctions that cannot be ruled out. In particular, immediate help must be available in case of incorporation or contamination by radioactive substances. For areas in which the danger of the incorporation of radioactive substances exists, activity concentrations in the air must be continuously measured. An alarm must be sounded if limits are exceeded. This in turn must be followed by suitable measures for the protection of the operating personnel (e.g., use of a respirator or immediate evacuation of the workspace).

Physical safety is increased further by regular medical examinations. According to § 62, Section 1 StrlSchV, the body dose or individual dose of persons who work in the control area must be determined.

5.6.4. Malfunction and Safety Analysis

An ingenious technical safety system allows all malfunctions that have any probability of occurring, to be controlled in such a way that the

a) Building; b) Hot cell; c) Outlet air stack; d) Off-gas stack; e) Overflow outlet; f) Cell outlet air/off-gas; g) Measuring/ agitation air; h) Container off-gas; i) Secondary cooling system; j) Primary cooling system; k) Chemicals input duct; l) Recooling unit; m) Operating compartment; n) Container with radioactive inventory; o) Batching tank; p) Chemicals supply; q) Contact plate; r) Tank surface with detectors; s) Cell cladding; t) External sealing

population and the operating personnel do not suffer any serious injury to health. Operational disorders and malfunctions that could occur in the plant must be examined in a *malfunction analysis*. Here, conditions in the plant during the course of operations must be analyzed systematically, and experience from comparable plants taken into account. The consequences of possible malfunctions should be examined carefully, and precautionary measures must be taken to control and contain the effects of damage. In the analysis of possible malfunctions, human error must be considered.

The following events must be taken into account as malfunctions in the design of a reprocessing plant:

- Disintegration of a fuel element with too short a decay time and thus a too high level of radioactivity
- Mechanical damage of vessels, equipment, facilities that serve to enclose radioactive substances, and safety facilities, damage due to crashing of loads
- Leakage
- Fire
- Explosion and exothermic chemical reactions
- Criticality events
- Failure of important cooling facilities that are important for safety
- Failure of energy and media supply
- Failure of off-gas and ventilation facilities
- Spontaneous breakdown of pressure vessels for media (i.e., water, gases, coolants, etc.) supply on the plant premises

All natural events that depend on the specific location of the plant, particularly earthquakes, must also be considered as design-determining malfunctions.

The *safety report* submitted in the licensing procedure serves to predict the time-dependent behavior of all barriers by the use of scientific methods. Here, among other things of special importance, changes in functioning of the hold-back mechanism of the barrier must be evaluated. Reliable bases for calculation must be obtained for the events and processes considered so that changes with time in the hold-back function of the barriers used, and thus in the release rates of radionuclides into the biosphere, can be derived quantitatively.

In the *licensing procedure*, the safety report must be displayed for public scrutiny. It serves as an essential document for both experts and authorities in the examination and granting or denying of a license. There are two differenct ways of conducting a safety analysis: the de-

terministic and the probabilistic methods. The most important elements and differences are presented in Figure 132. Currently, the deterministic method is being used almost exclusively for the licensing procedure. As in reactor safety research, an attempt is also being made in the case of reprocessing plants to supplement deterministic analyses with probabilistic methods in the assessment of the compatibility of the concepts involved.

5.6.5. Environmental Protection and Radiological Exposure

After being granted a license, every nuclear plant is subject to observation and supervision by state authorities during its entire lifetime. They must make sure that the operating company adheres to laws, as well as to other rules and regulations, and follows licensing conditions.

Representatives of the supervisory body or experts appointed by them can enter the plant at any time, inspect and examine it, and demand information from the licence holder. Both the supervisory body and the state licensing authority are, to the same extent, subject to supervison by the Federal Minister for Environment, Wildlife and Reactor Safety.

During normal operation, a minute fraction of the radioactive substances handled in the plant is released in a controlled way. This leads to a radiological burden on the plant surroundings, whose limits are stipulated in the radiation protection ordinance (Strahlenschutzverordnung) and the operating license. The calculated emissions, which as a rule are considerably higher than real emissions, result from plant-dependent emission conditions and location-specific meterological diffusion conditions.

For a reprocessing plant, the *radioecology* is determined exclusively by longerlived nuclides because of the preceding cooling time of the fuel elements. Calculation of the maximum possible radiation exposure is based on the following limiting conditions: operation of the plant for 50 years, emission at the approved rates of release, no reduction of activity other than through radioactive decay, and persons considered in the calculation must not only remain at the same location for 50 years (the place that exhibits the highest annual average activity) but also receive all their food from this location. Assumptions of this type are called conservative. They ensure that the result of the entire calculation rests on the safe side even when values used at individual points in this calculation are below those stated in various publications (e.g., the transfer factors for radionuclides).

The following exposure pathways are taken into consideration:

Exhaust air
- Direct irradiation from the exhaust air cloud: external β and γ radiation
- Direct irradiation from deposits on the ground
- Inhalation from the exhaust air cloud
- Deposits from the air on plants; consumption of milk, meat, and plant food

Wastewater
- Direct irradiation: swimming, boating, and sojourn at the waterfront
- Drinking water
- Fish consumption
- Use of river water for the cattle watering tank: consumption of milk, meat, and plant food

5.6.6. Radioactive Residual Substances and Waste

A plan must be prepared for the disposal of residual matter and waste that accumulate in a reprocessing plant. The concept must include a description of the type, nature, and amount of these materials; the concentrations of radioactive substances, stipulation of storage and conditioning; and evaluation of the safety aspects connected with this task (see Section 5.5).

Several measures are taken to achieve the final goal of radioactive waste treatment, namely, safe and long-term isolation from the biosphere. Thus, a process is required which yields minimum quantities of a waste that is as easy to treat as possible. At the same time, the various flows of waste material must be collected separately and subjected to different methods of treatment in accordance with the composition and nature of the materials [353]. Radioactive substances are separated from raw waste flows and enriched in a concentrate. The decontaminated flows are

Figure 132. Two different approaches for safety analysis

then returned to the process or released into the environment. For the conditioning of radioactive waste, see Section 5.5.2.

5.6.7. Decommissioning and Dismantling

In the case of planned or forced discontinuation of a reprocessing plant, considerable amounts of radioactive substances can still be contained in the plant even after the removal of the operating materials. Therefore, a reprocessing plant should be designed and built in such a way that, in keeping with radiation protection requirements, it can be secured or totally dismantled after final shutdown. For this reason, aspects of a total decontamination in the future must be taken into consideration when designing a plant. Factors of importance include stipulation of room size; use of building and other materials; and arrangement of hot cells, components, piping, and operating facilities.

5.6.8. International Coordination of Safety Regulations

The operation of reprocessing plants, radioactive waste management facilities, and intermediate and final storage is subject to rather similar criteria in countries using nuclear energy. Most important is the radiation protection of humans. The health hazards associated with the handling of radioactive materials had been recognized in the early days of the nuclear age. Since 1928, in combination with international radiology congresses (held every 3 – 5 years), efforts have been made to found an international expert body with the aim of harmonizing radiation protection. The International Commission on Radiological Protection (ICRP), founded in 1950, developed from these efforts and now dominates the area of radiation protection worldwide. This organization issued two basic recommendations in 1953 and 1985 [354], which increasingly influenced legislation for the protection of employees–and hence the population –from ionizing radiation [355]. Noteworthy is the high degree of international agreement on the basic problem of radiation protection and its biological principles [356]. This agreement is independent of social system; i.e., technical safety criteria for nuclear technology are similar worldwide.

Recommendations of the ICRP are based on expert judgement; radiation protection should be controlled on the basis of joint scientific principles and joint formulated protection aims within certain limits. The EC incorporated these recommendations into its basic norms for the protection of employees and the population, and developed regulations that are mandatory for all member states. The EC countries are also at liberty to issue more rigorous regulations for radiation protection, such as those issued in the German Radiation Safety Ordinance (Strahlen-

schutzverordnung). In countries using nuclear energy, legislation concerning radiation protection leads to the interaction of official and unofficial bodies at regional, national, and international levels with contributions from scientific societies, professional assemblies, administrative bodies, ministry offices, and professional experts from governmental consultant committees. This intermingling is also observed at an international level with the IRCP as highest authority.

The United Nations has also set up a commission of experts from 20 member states [United Nations Scientific Committee on the Effects of Atomic Radiation (UNSCEAR)] to control radiation exposure and describe its effects. The WHO is also active in radiation protection. The International Atomic Energy Agency (IAEA) in Vienna organizes international symposia on the safe use of nuclear energy and publishes regulations for the operation of nuclear power plants. Finally, the work of the Nuclear Energy Agency of the Organization for Economic Cooperation and Development (OECD/NEA), located in Paris, is also available as reference material.

The effect of all these influences leads to laws, guidelines, standards, and regulations that are virtually identical in countries with nuclear energy programs. The outcome of these regulators is always an atomic energy law for the safe use of nuclear energy. Second in rank are laws concerning the handling of radioactive waste.

Examples are Waste Policy Act, Fed. Reg. 10 CFR Part 960, 1982 and Amendments Act of 1987; Regles Fondamentales de Surete, France, 1984; Projekt Gewähr, Switzerland, 1985; Law on activities in the nuclear field, Sweden, 1984; Waste Disposal Policy, Cmnd 8607, United Kingdom, July 1982.

For occupational health the following rules hold [357]:

1) No work is allowed unless a net benefit can be demonstrated.
2) Radiation exposure should be kept as low as possible with regard to scientific and social factors.
3) The dose equivalent for a single person should not exceed the recommended limiting values.

As a consequence, virtually all countries that build or operate reprocessing plants employ the same industrial and administrative safety regulations. Listing specific regulations is beyond the scope of this article.

In addition, official hearings are obligatory in nearly every country. Here, the population has the opportunity to express doubts and concerns to state regulatory authorities. Examples are the Windscale hearing (held in 1977) concerning the construction of the THORP reprocessing plant in England, and the energy policy debate on the expansion of a reprocessing plant at La Hague. This debate took place in the French Parliament in October 1981, on the basis of the so-called Castaing Reports. *Reprocessing plants* are in operation in the United Kingdom, France, Japan, China, the former Soviet Union, the United States, and to a lesser extent, in India. Small reprocessing plants in Germany, Belgium and Italy were closed down years ago.

Laws and safety regulations governing *installations used for waste disposal* are of greater public interest than those concerning reprocessing plants. The basic regulations are similar in every country [358]. The respective national atomic energy laws define the limiting framework sanctions for nuclear plants, their closure, and the disposal of radioactive waste. Differences exist with regard to responsibility for the disposal of waste material. In most countries the producer is responsible for the safe disposal of radioactive waste, but the state always checks that disposal has been carried out correctly. In several countries (e.g., Germany), radioactive waste disposal occurs under state responsibility. In some countries (e.g., Sweden, Switzerland, Germany) the use of nuclear energy depends on proof that permanent and safe disposal of the radioactive waste can be achieved. Other countries have less stringent regulations; normally, appropriate intermediate storage of the spent fuel elements or the radioactive waste is sufficient.

The following societies and organizations in various countries are responsible for the disposal of radioactive waste:

Belgium: ONDRAF, responsible for total waste management, founded in 1981.

Federal Republic of Germany: Bundesamt für Strahlenschutz, Salzgitter, responsible for final waste disposal. The "Deutsche

Gesellschaft zum Bau und Betrieb von Endlagern für Abfallstoffe" (DBE), Peine, is engaged as a so-called third party in the installation of federal facilities for the long term storage and final disposal of radioactive waste.
France: ANDRA, responsible for total waste management, founded in 1979.
United Kingdom: NIREX, responsible for total waste management, founded in 1982.
India: Atomic Energy Authority, state controlled.
Italy: NUCLECO, responsible for total waste management, founded in 1981.
Japan: Power Reactor and Nuclear Fuel Development Corporation (PNC), responsible for all aspects of fuel cycle.
Canada: Atomic Energy Authority (AECL), state controlled.
The Netherlands: COVRA, responsible for total waste management, founded in 1982.
Sweden: Swedish Nuclear Fuel Supply Company (SKBF), responsible for total waste management; KBS, a subsidiary of SKBE, is responsible for all R & D work.
Switzerland: NAGRA, responsible for total waste management, founded in 1972.
Spain: Junta de Energia Nuclear (JEN), state controlled; total waste management was transferred to a state-owned society, ENRESA, in 1985.
The former Soviet Union: Use of Atomic Energy, state committee.
United States: Department of Energy, with industrial subcontractors, based on the Radioactive Waste Policy Act of 1982.

6. Nuclear Fusion

Fusion of light nuclei is by far the most important process of energy release in the universe. The sun and most of the other stars are powered by the fusion of four hydrogen nuclei into one nucleus of helium, which was named after the sun (Greek: *helios*). Every such process releases an energy of 26.72 MeV (6.7 MeV per nucleon). Moreover, fusion processes are responsible for the generation of elements in the stars. This is obvious from the dependence of the nuclear binding energy per nucleon on the atomic mass number (see Fig. 133). Fusion energy is released in the fusion of light elements, while fission energy can be obtained from the fission of very heavy elements. Nuclei of medium atomic mass such as iron and nickel (Ni) have the lowest mass per nucleon (i. e., the highest binding energy) and hence are stable elements, because every rearrangement of their nuclei leads to a state of higher energy.

Figure 133. Nuclear binding energy per nucleon $\Delta E/N$ as function of the nuclear mass number A

On earth, up to now fusion energy has only been released in an uncontrolled way by the test explosion of hydrogen bombs. The fusion reactor based on the controlled operation of thermonuclear fusion, however, is a very important option for future energy supply, since the fuel is practically inexhaustible and this new energy source is environmentally acceptable. The enormous research efforts into controlled thermonuclear fusion, which in the early 1950s began in the United States, the United Kingdom and the former Soviet Union, aim at the development of a reactor that produces net energy from the fusion of hydrogen isotopes in a high temperature plasma. Because of the extremely difficult physics and technology problems which still have to be solved, it is expected that it will take more than half a century until this commercially attractive and environmentally acceptable fusion reactor will be available.

6.1. Fusion Physics

Normally, positively charged nuclei interact by their repulsive Coulomb forces unless their rela-

tive velocity is high enough to tunnel through the Coulomb barrier. Hence, fusion reactions occur practically only between light nuclei. Among the nearly 80 possible fusion reactions the following are most important:

$$D + D \longrightarrow {}^{3}_{2}He + n + 3.267\,MeV$$

$$D + D \longrightarrow T + p + 4.032\,MeV$$

$$D + {}^{3}_{2}He \longrightarrow {}^{4}_{2}He + p + 18.351\,MeV$$

$$D + T \longrightarrow {}^{4}_{2}He + n + 17.586\,MeV$$

$$T + T \longrightarrow {}^{4}_{2}He + 2n + 11.327\,MeV$$

$$p + {}^{11}_{5}B \longrightarrow 3\,{}^{4}_{2}He + 8.664\,MeV$$

$$p + {}^{6}_{3}Li \longrightarrow {}^{3}_{2}He + {}^{4}_{2}He + 3.890\,MeV$$

where p denotes proton, n neutron, D deuterium, and T tritium. The energy, which is released as kinetic energy of the reaction products, is also indicated, with 1 MeV = $1.6022 \cdot 10^{-13}$ J. This energy release – normalized to the mass involved – is more than six orders of magnitude higher than that of typical chemical reactions such as carbon oxidation in fossil fuels. This reflects the fact that nature – in releasing thermonuclear fusion energy in the stars – has chosen the process with the minimum mass consumption.

For thermonuclear fusion reactors the D – T reaction is by far the most attractive one. It has the highest fusion cross-section (with a maximum at relatively low energy) and also a very high energy release per reaction. One fifth of the energy is carried away by ${}^{4}_{2}He$ (alpha particle), while 80 % is released as kinetic energy of the neutron. Hence, with this reaction the highest power densities in a fusion reactor can be achieved (see Fig. 134).

Although the resources of deuterium (concentration of 0.015 % in natural hydrogen) are nearly inexhaustible and geographically equally available, tritium does not naturally occur in sufficient quantities, because it is radioactive (half-life 12.35 a). Using the fusion neutrons from the D – T reaction the tritium required is gained in the reactor breeding reactions with lithium:

$${}^{6}_{3}Li + n \longrightarrow T + {}^{4}_{2}He + 4.8\,MeV$$

$${}^{7}_{3}Li + n \longrightarrow T + {}^{4}_{2}He + n' - 2.47\,MeV$$

Natural lithium contains 7.42 % ^{6}Li and 92.58 % ^{7}Li. Lithium is, as deuterium, geographically equally available, also in the oceans. Hence, deuterium and lithium are the actual fuels for the fusion reactor, tritium is only internally produced in the reactor system. The first tritium inventory, however, has to be supplied from fission reactors.

Because of the possible safety and environmental risks of the D – T reaction, which are related to the use of tritium as radioactive fuel component and the activation of structural materials by the fast fusion neutrons, the other fusion reactions listed before are considered, too. As shown in Fig. 134, the other fusion reactions have a much lower fusion power density, and their control involves higher physical and technological problems than those encountered with the D – T reaction.

The Figure 134 moreover, shows that high fusion powers are obtained at high temperature (or energy) of the reaction partners, which is in the range of 15 keV (or about 170×10^{6} K since 1 eV corresponds to 11 604.5 K). At these high temperatures the matter is in the plasma state, i.e. all particles are charged. At sufficiently high plasma densities, the Coulomb collisions between these charged reaction partners are so frequent, that the collisions have a Maxwellian velocity and energy distribution, hence a temperature. Since the fusion cross-section strongly increases with the temperature, "thermonuclear fusion" occurs if the temperature of the plasma has been made sufficiently high by supplying a large quantity of energy.

For a selfsustained "thermonuclear burn" the unavoidable energy losses due to radiation and heat conduction must be balanced by part of the fusion power in order to sustain temperature and density. Bremsstrahlung losses are such unavoidable radiation losses, which are related to the deceleration of electrons by Coulomb interaction with other charged particles in the plasma. Other losses are caused by line and recombination radiation from impurities, by heat conduction, or by plasma turbulence and instabilities. Since for the D – T reaction one fifth of the fusion power is released in the (positively charged) alpha particles, while four fifth are carried away by the neutrons, thermonuclear burn occurs if the *ignition condition* is fulfilled. This criterion

requires power balance between the heating of the plasma by the alpha particles formed and all unavoidable power losses. If it is assumed that the plasma is not deluted by impurities, hence is a pure D – T plasma, the ignition criterion is simply expressed by the product of the plasma pressure p and the energy confinement time τ_E to be greater than a numerical value, which only depends on the temperature T of the plasma. For the D – T reaction a minimum is reached at a temperature of about 15 keV, such that the D – T ignition criterion reads $p \cdot \tau_E \geq 1$ MPa · s.

The energy confinement time τ_E is the characteristic energy loss time constant, which qualifies the thermal insulation of the plasma confinement. It is simply given by the ratio of the plasma energy density and the heating power necessary to sustain the plasma parameters.

Figure 134. Power densities P of different fusion reactions at pressure limitation versus plasma temperature T, normalized to the maximum of the D – T reaction.

Although the energy of the fusion neutron is not taken into account for the energy balance underlying the D – T ignition criterion, the main aim of worldwide thermonuclear fusion research is to fulfill this criterion. Since the plasma pressure p is given by the plasma density n and the temperature T_i and T_e of ions and electrons, respectively, through $p = n \cdot k_B (T_i + T_e)$, the ignition criterion gives the minimum conditions for the three key parameters of the plasma – the ion temperature T_i, the plasma density n and the energy confinement time τ_E – necessary for a self-sustained "thermonuclear burn" of the plasma. Typical plasma densities are in the range of $n = 10^{20}$ m^{-3}, and temperatures in excess of 15 keV have been reached, hence energy confinement times of more than 2 s are necessary. Although the critical value of each of these parameters was reached and usually substantially exceeded separately in different experiments, the simultaneous fulfillment of all conditions has not been achieved up to now. This is the aim of worldwide investigations in close international cooperation.

6.2. Plasma Confinement and Status of Fusion Research

Two key problems must be solved to achieve net power from any fusion system. A sufficiently dense and pure D – T plasma has to be heated to ≥ 10 keV ($> 10^8$ K) and be confined against energy losses for a certain minimum time. Two very different concepts exist for plasma confinement: (1) *magnetic confinement*, which has been studied from the beginning of fusion research in different configurations, and (2) *inertial confinement* (laser pellet fusion or ion beam pellet fusion).

6.2.1. Magnetic Plasma Confinement

A hot, highly ionized plasma is a good electrical conductor. A plasma with an electron temperature of 10 keV has an electrical conductivity about 20 times as high as that of metallic copper. Correspondingly, plasmas can carry strong currents and can be influenced by magnetic fields. In a microscopic view, charged particles (electrons and ions) gyrate around magnetic field lines. Therefore, they are essentially bound to the field lines but they can freely flow along them. In the linear or "open" magnet configurations, field lines leave the plasma and the plasma particles can escape. Fusion approaches with linear configurations such as mirror machines and

linear pinches suffer from such end losses. In contrast, when the plasma forms a toroid and all the field lines stay within the plasma end losses can be avoided. In the "closed" toroidal machines the magnetic field lines generate an assembly of nested toroidal magnetic structures that can contain the plasma. The poloidal (located around the minor torus circumference) and the toroidal magnetic field components generating these configurations must be tailored to guarantee plasma equilibrium (balance of forces exerted by the magnetic fields and by the plasma) and at least gross plasma stability. In practice, often auxiliary outer magnetic fields or currents, including also a shaping of the plasma cross-section, are applied to achieve these objectives. The basic magnetic field components in toroidal devices can be produced, either *solely by currents in conductors* (magnetic coils) *surrounding* the plasma or with a strong additional *current component in the plasma*. Machines of the first type are the Stellarators, those of the second type are the Tokamaks and Reversed Field Pinches. In a long-lasting selection process that has gone on since the beginning of fusion research 35 years ago, toroidal confinement devices have been essentially successful. The Tokamak particularly is considered the most promising contender for a fusion reactor.

Figure 135. Schematic of the Tokamak principle
The poloidal magnetic field is produced by the toroidal plasma current induced in the plasma by a transformer. The toroidal field is produced by D-shaped coils. The coils for the vertical magnetic field are not shown.
a) Transformer winding (primary circuit); b) Plasma current (secondary circuit); c) Poloidal magnetic field; d) Toroidal magnetic field; e) Resultant helical field (twist exaggerated); f) Toroidal field coils; g) Ion transformer core

In toroidal devices the density of the plasma is rather low (ca. $10^{20}\,\mathrm{m}^{-3}$), which is about 10^5 times lower than that of a gas under atmospheric pressure. At the temperature envisaged ($\geq 10\,\mathrm{keV}$) plasma pressures reach several atmospheres. They must be much smaller (5 – 10 %) than the pressure of the confining magnetic field to achieve magnetohydrodynamic stability. So the ultimate strength of the magnetic field that can be generated in superconducting coils ($\leq 12\,\mathrm{T}$) eventually determines the upper limits of plasma density. According to the ignition criterion, τ_E must typically be a few seconds. Because the fusion power densities in such dilute plasmas are low (some watts per cubic centimeter), huge plasma volumes have to be used in toroidal fusion reactors.

Tokamak. The Tokamak is the most advanced fusion system with respect to plasma physics. The Tokamak principle was developed initially at the Kurchatov Institute in Moscow in the 1960s. Because of the spectacular results, particularly the achievement of high plasma temperatures, Tokamaks spread all over the world in the 1970s. The very successful, and currently largest, fusion system JET (Joint European Torus) in Culham, UK is a Tokamak. A schematic of the Tokamak configuration is shown in Figure 135. The Tokamak uses magnetic fields that are a combination of a strong toroidal field with a weaker poloidal field (field lines circling around the torus core). The *toroidal field* of several teslas is produced by magnetic coils placed outside the toroidal vacuum vessel, whereas the *poloidal field* is generated by a strong current transiently induced in the plasma by the action of a transformer. This current also produces an initial heating of the plasma. The field line pattern resulting from the combination of both field components is a helix with a low pitch angle. A third component, a *vertical magnetic field*, produced in a set of poloidal coils, is necessary to keep the plasma in a well-centered equilibrium position and to shape the cross-section of the plasma for optimum confinement properties. The transformer principle does not allow a continuous stationary plasma current. Therefore, all Tokamaks work in a pulsed mode. For a reactor, steady-state operation appears to be necessary, mainly for technical and economic reasons (simplification of engineering design, improvement of reactor availability, avoidance

of cyclic stresses and of intermediate energy storage). Experiments are in progress to drive a stationary current by means of electromagnetic waves or neutral particle injection.

The current ohmic heating of the Tokamak plasma becomes inefficient at increasing temperature T because the electrical conductivity of the plasma is proportional to $T^{3/2}$. To approach ignition temperatures, additional heating methods such as neutral deuterium beam injection or injection of radio-frequency waves into the plasma are used in Tokamak experiments.

Connected with the energy confinement time, the existence of impurities in the plasma is one of the most serious problems in magnetic confinement devices. Even when sufficient gross plasma confinement is achieved, impurities will be released at the vacuum wall by particles escaping from the plasma by diffusion. Because these impurities are mainly neutral atoms, they can penetrate the plasma. As a result, radiation losses are dramatically increased and energy confinement is thus impaired. Various techniques are used to reduce the impurity influx. In normal Tokamaks, diffusive plasma extension is cut off by a limiter, which may be a material boundary or a magnetic limiter. In more advanced *divertor Tokamaks* the plasma edge sheath is sucked up by a magnetic system, the divertor. The plasma particles and impurities are magnetically guided to an external divertor chamber and deposited there on target plates. Such divertors are necessary anyway in toroidal reactors to remove burned fuel.

Stellarator. In the Stellarator, helical magnetic fields for confinement are produced solely by *external coils*. Because of the lack of both a net toroidal current in the plasma and a transformer, the Stellarator configuration is naturally suited for steady-state operation. Topologically somewhat different magnetic configurations of the Stellarator class can be generated by particular arrangements of coil sets, leading to Torsatrons, Heliotrons, and different classes of Stellarators. In the *advanced Stellarator concept* (Fig. 136), nonplanar coils are used in a toroidal system of large aspect ratio, offering the advantage of a modular system that is more accessible than the Tokamak system. Heating in the Stellarator is performed with nonohmic methods. Otherwise, with respect to plasma properties and impurity problems, the Stellarator has much in common with the Tokamak, to which it may be a promising alternative.

6.2.1.1. Status of Magnetic Confinement Fusion

Efforts to develop fusion as a future source of energy are underway worldwide. The bulk of the effort is concentrated in four large programs of about equal size: in the EC, in Japan, in the former Soviet Union, and in the United States. In *Western Europe*, research and development on controlled fusion is coordinated by Euratom. The program is shared by the fusion centers of the EC and by Sweden and Switzerland. The program concentrates on the development of the Tokamak system including development of the technological components necessary for a future reactor. The largest single experiment in the European program (and in the world) is the Joint European Torus (JET) at Culham, United Kingdom. Alternative systems, pursued with somewhat lower priority, are the Stellarator (MPI, Garching, Germany) and the Reversed Field Pinch (Padua, Italy). Supplementary research is carried out on rather large Tokamak devices in national laboratories of the EC states (Asdex Upgrade, Garching, Germany; Tore-Supra, Cadarache, France).

Similar programs in fusion research with a concentration on the Tokamak are in progress by the other three parties and have led to large Tokamak devices: TFTR (United States), JT 60

Table 66. Plasma parameters reached in JET, compared with those required in a Tokamak fusion reactor

	η_{eo}, 10^{20} m^{-3}	T_{io}, keV	τ_E, s	$\eta_{io} T_{io} \tau_E$, 10^{21} keV · s/m^3	$\langle\beta\rangle$, ∗ %
Reached in JET	0.4	22	1.1	0.9	2
Needed for a reactor	2 – 3	10 – 20	1 – 2	5	∼6

∗ $\langle\beta\rangle$, the ratio of the plasma pressure to the pressure of the confining magnetic field, characterizes the utilization of magnetic field energy.

(Japan), and T 15 (Russia). More than ten Stellarator experiments, mostly small scale, are in operation worldwide, and five Stellarators are under construction.

The currently operating Tokamaks including JET and TFTR are still pure plasma experiments, with hydrogen or deuterium. The components necessary for a fusion reactor, i.e., blanket, shield, and tritium systems, have not yet been installed. Technological developments only exist with respect to the magnets. Tokamaks with superconducting magnets are operating in France (Tore-Supra) and in Russia (T 7 and T 15).

The status of Tokamak research is well represented by JET (Fig. 137), which became operational in 1983. The goal was to study plasma behavior–heating, stability, and confinement – in a parameter region close to reactor conditions and at plasma dimensions approaching those of a reactor: (plasma diameter horizontally 2.5 m, vertically 4 m; major torus radius 6 m). The JET has routinely operated with currents above 5 MA, which can be maintained for 2 s. In 1986, a plasma ion temperature of 100×10^6 K and an energy confinement time of 0.5 s could be reached at a heating power of 8 MW. These results were remarkable because they indicated progress in thermal insulation of the plasma. In earlier experiments the confinement times were lower and decreased with increasing heating power. These results were made possible by modification of the magnetic structure at the plasma edge, thus reaching a favorable "high-confinement regime" (H-regime). The regime was discovered in the large divertor Tokamak Asdex at Garching (Germany). However, in JET, as in other Tokamaks, the confinement is still dominated by anomalous heat conduction, mainly due to the plasma electrons. Despite long-lasting and extensive research, a basic understanding of this obviously complex phenomenon is not yet available.

Figure 137. JET (Joint European Torus)
a) Vacuum vessel; b) Toroidal field coil; c) Outer poloidal field coils; d) Inner poloidal field coils; e) Ports for neutral beam injection; f) Transformer limb

Over the last years (1987 – 1997), additional heating with *neutral beam injection* up to 21 MW and with *ion cyclotron resonance* up to 11 MW has been applied. At a total input power of 30 MW, ion temperatures of 32 keV and energy confinement times of 1.1 s have been obtained. With respect to impurity control, great progress was achieved by covering the inside walls of the JET vacuum vessel with beryllium instead of carbon, as done before. Radiation losses were reduced, and the neutron density could be increased almost to reactor-relevant values. In Table 66 the plasma data reached in single discharges are compared with those needed for a fusion reactor. In discharges of the H-regime, for very short times (ca. 0.1 s), record values of the fusion reaction product $\eta_i T_i \tau_E$ of 0.9×10^{21} keV · s/m^3 and a power amplification factor Q of 0.9 (extrapolated for D – T operation) were attained (Q is the ratio of fusion power re-

leased to total heating power; $Q = 1$ means break even and $Q = \infty$ ignition in a D – T reactor). The limitation in time was caused by an unavoidable impurity backflow from the divertor, which should be overcome in the future (1992) by means of additional pumping in the divertor. The (1990) status at JET and at TFTR is shown in Figure 138 ($\eta_i T_i \tau_E / T_i$ diagram), which also illustrates the plasma physics path toward controlled fusion, beginning with the first Tokamak experiments on the T 3 device in the former Soviet Union.

Figure 138. Performance of Tokamaks (1965 – 1990)
The fusion product $n_i \tau_E T_i$ is the product of the central ion density, the confinement time and the central ion temperature reached in single experiments.

Q_{DT} is the ratio of the peak fusion power to the total input power, translated for a D – T mixture. (The experiments were performed in pure deuterium.)

The latest JET results indicate that ignition can be achieved without further complications in a somewhat larger post-JET device such as the Next European Torus (NET) or International Thermonuclear Experimental Reactor (ITER) (see Section 6.2.1.2). Nevertheless, a concluding experimental stage is foreseen on JET in which, for the first time in a large facility, deuterium – tritium fuel has been used, thus initiating a decisive phase for fusion research in the magnetic confinement approach.

6.2.1.2. Further Development of Magnetic Confinement Toward a Fusion Reactor

Based on favorable results with JET, TFTR, and other large Tokamak devices, the final objective is an energy-producing Demonstration Reactor (DEMO) with only one intermediate experimental facility. In the framework of the Euratom program, another large Tokamak facility NET (Next European Torus) was foreseen. Design and construction work for NET has been going on since 1983. In the meantime, stimulated by the Reagan – Gorbachev initiative (Geneva 1985), a joint venture called the International Thermonuclear Experimental Reactor was initiated by the International Atomic Energy Agency in 1987, and subsequently, conceptual design activities began under the auspices of the IAEA (1988). The ITER takes advantage of NET planning as well as of the earlier INTOR concept of the IAEA. Partners in the ITER program are the EC, the United States, Japan, and Russia.

The ITER is expected to confirm fully the scientific feasibility – and to address the technological feasibility – of fusion power via the magnetic fusion approach. Consequently, the machinery must be designed for controlled ignition and extended burn of deuterium – tritium plasmas. It must also demonstrate and perform integrated testing of components required to utilize fusion power for practical purposes. Among other items, ITER will be equipped with superconducting magnets; refueling and ash removal systems; test blankets; and tritium-handling systems, and should already generate 1 GW of fusion power. After definition of the concept, the design phase began in 1989 at the MPI Garching with international teams of scientists and engineers. About 13 years of design and construction work is expected until ITER becomes operational.

The heart of the ITER facility is the Tokamak device represented in Figure 139. Its principal parameters can be summarized as follows:

Plasma major radius R	6.0 m
Plasma half-width at midplane a	2.15 m
Toroidal field on axis B_0	4.85 T
Nominal maximum plasma current I_P	22 MA
Nominal fusion power P_f	1000 MW

Figure 139. Basic elements of the ITER Tokamak
a) Cryostat; b) Poloidal field coils; c) Toroidal field coils; d) Vacuum vessel; e) Vertical port; f) Divertor; g) Blanket and shield; h) Horizontal port; i) Vacuum pump duct

The design features and parameters are determined by the objectives, such as attainment of ignition and extended burn, plasma stability, impurity control, and current drive, and also by safety considerations (particularly in tritium handling) and cost minimization. A preliminary estimate of the capital cost in 1989 amounted to $\$4.9\times10^9$.

6.2.2. Inertial Confinement Fusion

Since ca. 1965, another approach to controlled fusion power has been pursued, particularly in the United States, Japan, and France. In inertial confinement fusion (ICF) or *pellet fusion*, energy is produced in a series of microexplosions. The basic idea is the rapid implosion of a solid deuterium – tritium fuel pellet by irradiation with laser or ion beams, so that a hot, very dense core develops that fuses before the pellet disintegrates. Generally, magnetic confinement fields are not needed.

For the implosion, two concepts are presently being investigated. In *direct drive*, solid spherical pellets of complicated shell structure (see Fig. 140) are irradiated directly by very intense laser or ion beams. In *indirect drive*, laser light is focused into a hollow shell, where it is converted into X-rays (hohlraum radiation). This radiation, in turn, compresses the pellet which is centrally located within the shell. In both cases a rapid ablation of the outer pellet surface develops. The repulsion of the rapidly expanding plasma corona should first compress the pellet core to about $10^3 - 10^4$ times solid-state density and then adiabatically heat it to initiate an outgoing, self-sustaining fusion burn wave. Provided a sufficient fraction of the fuel is burned before the pellet cools down, the energy gain (ratio of nuclear energy output to driver energy output) may make up for the very low efficiencies of the driver systems. The fuel pellets must be very small to keep the explosive yield within technologically acceptable limits, because the reactor chamber and the blanket must be able to withstand the stress resulting from repetitive pellet explosions.

Laser Fusion. In the current, most advanced laser fusion experiments, neodymium – glass lasers are usually applied. However, their emission at a wavelength of 1.05 μm is not well suited to pellet compression. Thus their infrared light is

generally converted to 0.53 or 0.35 μm by crystal converters, to improve the laser – target coupling and avoid the generation of fast electrons that would cause unfavorable preheating of the pellet core. The largest laser facilities are NOVA (100 kJ in laser pulses at 1.05 μm, Livermore, United States) GEKKO (50 kJ, Osaka, Japan), and PHOEBUS (20 kJ, Limeil, France). A number of medium- and small-sized facilities in the kilojoule to 100-J range also exist (United States, China, UK, France, Germany, Italy).

Many serious problems must be overcome: laser power of tens of terawatts must be focused to submillimeter dimensions to reach peak power densities of $> 10^{16}$ W/cm^2 at the pellet surface. Furthermore, irradiation has to be with spherical symmetry and high uniformity, otherwise instabilities causing disturbances of the pellet surface would impair the symmetry of the compression. In experiments with direct drive, up to 24 or even 60 laser beams, distributed over the pellet surface, have been used. The distribution is achieved by complicated beam splitting and aiming systems. Optical smoothing methods are also successfully applied.

Considerable compression factors up to 100 – 200 times liquid density have been obtained in both drive methods by using multilayered capsules filled with D – T gas. In a high-temperature mode using direct drive, T_i of about 10 keV and high fusion neutrons, yields of 2×10^{13}, but only low compression to liquid density, were attained in NOVA and GEKKO. For indirect drive, the best performances were obtained with NOVA leading to ion temperatures of 1.9 – 2.3 keV, about 100 times the liquid density, and a deduced $\eta\tau$ of $(2-4)\times10^{20}$ s/m^3. The $\eta\tau$ is comparable with that attained in advanced Tokamaks, but in ICF, higher values must be reached, mainly because of the poor driver efficiencies. However, Nd – glass lasers are not well suited for energy production with ICF. Their efficiency, in the 0.1 % range, is too low. New lasers with short pulse duration ($< 10^{-9}$ s) and high efficiency (≈ 10 %) must be developed. A leading candidate for future use is the KrF laser, which should reach efficiencies of 2 – 5 %.

Ion Beam Drivers. Light and heavy ion beams are also being considered as drivers. Multimegajoule pulses of light ions can be produced rather easily, and the efficiency can be made sufficiently high (15 – 30 %), but very high voltages (multimegavolts) are required. Beam transport and beam focusing on the pellet will be difficult, particularly because they must be performed during repeated thermonuclear blasts in future reactors.

The *light-ion technologies* have been developed mainly at Sandia (United States) and Osaka (Japan). In the PPFA-II device at Sandia the use of megajoule pulses of lithium ions for ICF is being developed. Significant advances have been achieved, but the progress is relatively slow. Major problems are the beam transport and the beam focusing onto the pellet surface.

Heavy ion beams as drivers may have better prospects. They have a shorter stopping range in the pellet and so the beam – target coupling should be more efficient. Furthermore, the efficiency of heavy ion accelerators could be made relatively high (about 25 %). Research on heavy ion drivers is still at an early stage. Some work is in progress on the large linear accelerators at Berkeley, United States, at Moscow and at the GSI in Darmstadt, Germany.

6.3. Fusion Reactors as Energy Sources

The development of an economical electricity-producing source based on fusion power is one of the most difficult and lengthy endeavors ever undertaken in the history of science and technology. After about 45 years of fusion research, even the scientific feasibility of a fusion reactor has not yet been proven. In the most advanced fusion devices an improvement in the plasma confinement parameter of about a factor of ten (see Fig. 138) still has to be achieved. Furthermore, difficult technological problems with plasma control and peripheral reactor components must be solved. To prove the scientific and technological feasibility of fusion, the technical practicability, reliability, and safety of all necessary components of a fusion power plant, including the operation of a full demonstration plant (DEMO), must be shown. To achieve this objective, a sequential development strategy based on prototype machines of increasing size has to be followed, which in the Tokamak line may consist of the sequence JET – ITER (or NET – DEMO). Even with this optimistic strategy consisting of

only three steps, fusion power that is commercially available to a significant extent cannot be expected before the middle of the next century.

6.3.1. Fusion Power Plants

Magnetic Confinement Fusion. Preliminary studies of fusion power plants have been made, beginning in the early 1970s, some of which led to rather comprehensive fusion reactor designs, mostly for Tokamak reactors. These studies rely on numerically extrapolated D – T plasma confinement properties and contain the layout of technical reactor components, estimates of material needs, fuel requirements, estimates of investment and energy costs, and initial assessments of environmental and safety aspects and, particularly, of the radiological hazard potential of future fusion reactors.

The basic structure of a fusion reactor is about the same in all approaches to magnetic confinement fusion. Figure 141 shows a simplified schematic of a Tokamak fusion reactor, representing a cross-section of the toroidal arrangement. The processes in a fusion power plant are illustrated in Figure 142. The hot fusion plasma with a temperature of $100-200\times10^6$ K and a density of 10^{20} m^{-3} is surrounded first by a metallic, possibly layered wall. The next element in a toroidal shell structure is the blanket of about 0.5 – 1-m thickness, composed of many closely fitted modules. In the blanket modules, lithium is contained in the form of either liquid lithium metal, solid lithium compounds, or molten lithium salts. The blanket has many functions; it moderates the neutrons that leave the fusion plasma and penetrate the blanket, and the heat produced is extracted by a coolant. Furthermore, according to Equations (21) and (22) (see Section 6.1), tritium is produced, which is used as a fuel after extraction, purification, and processing outside the reactor. Surrounding the blanket, a shield absorbs the remaining neutrons and γ radiation to protect the magnets against excess heat. The location of the primary vacuum containment has not yet been decided. A vessel that directly surrounds the plasma as in present experiments, may not be feasible for a fusion reactor because it is exposed to neutron damage and stresses. Of the different options, a primary vacuum containment just behind the blanket, but inside the toroidal coils, is favored. The *toroidal magnetic field coils* are expected to be fabricated from superconductors, because normal conducting coils would require too large a fraction of the power output. Additional coil systems produce time-varying magnetic fields. These are necessary for plasma equilibrium and initial heating (*poloidal field coils* and *ohmic heating coils*), as well as for ash removal (*divertor coils*).

Figure 141. Basic construction of a Tokamak reactor (Starfire cross-section showing the magnetic coil configuration and parts of the vacuum equipment.)

Since the inherent heating of the Tokamak is insufficient to reach ignition, additional heating methods, such as neutral beam injection or wave heating, must be applied. After ignition is reached, the current must be sustained to allow a continuous "burn" of the plasma, in contrast to the pulsed Tokamak operation in present-day experiments. Methods for current drive envisaged are, again, wave heating or neutral beam injec-

Figure 142. Schematic of functions in a fusion reactor showing very simplified fuel circuits
a) Injector; b) Nuclear fusion; c) Gas purification; d) Blanket; e) Tritium separation; f) Energy transformation

tion. The burned fuel and the fuel lost by diffusion must be replaced continuously. Replacement injection will be performed with pellets made of solid deuterium – tritium or by gas puffing.

The heat that is generated in the first wall, in the blanket, and in the shield (predominantly by fusion neutrons) is conventionally converted to electrical energy by means of a secondary coolant loop, heat exchangers, turbines, and electrical generators.

The *fuel handling* and *fuel circuits* in the fusion power plant are shown in Figure 142. A fusion power plant should be self-supporting with tritium fuel, so a sufficient tritium breeding ratio B (B = rate of tritium production to rate of tritium consumption in fusion) has to be achieved in the blanket. Calculations for different classes of breeding materials (e.g., Li, Li_2O, $Li_{17}Pb_{83}$ with 90 % ^6Li) in design blanket modules give breeding ratios between 1.2 and 1.4. These calculations were carried out for the International Tokamak Reactor (INTOR) design. Such breeding ratios are high enough to reach doubling times of the tritium inventory on the order of months.

Fusion reactors based on magnetic confinement are relatively large in size and in power output. Test reactors of small size are not feasible because some constraints of fusion physics, technology, and economy can be fulfilled only at large torus dimensions. The energy confinement, for example, varies roughly with the square of the minor torus radius. Furthermore, critical limits for the neutron and heat load of the first wall of the reactor do not permit a very compact or small reactor with high wall load. Even with the currently favored first wall (neutron) loads of 1 – 5 MW/m^2, the first wall must be replaced two to four times during the lifetime of the reactor. Thus fusion power densities in the reactor core of only ca. 1 – 5 MW/m^3 can be expected (power densities in fission reactors are about two orders of magnitude higher). From an economic point of view, electrical power outputs of 1 – 2 GW are preferred because the very expensive and complicated components–blanket, shield, superconducting coils–should enclose as high a fusion power as possible. Power plants based on the stellarator may be even larger, because the Stellarator requires higher aspect ratios (major torus radius/minor torus radius) than the Tokamak for stable plasma confinement.

The main characteristics of conceptual commercial Tokamak reactors are:

Thermal power	2 – 5 GW
First wall minor radius (vertical elongation of first wall cross-section ≈ 1.6)	1 – 2 m
Major radius	5 – 8 m
Strength of toroidal magnetic field in plasma center (produced with superconducting D-shaped coils)	3 – 8 T
Plasma current	10 – 20 MA
Neutron loading of first wall	1 – 5 MW/m^2
Total heating power	50 – 90 MW
Overall efficiency	0.3

Figure 143 shows the planned Tokamak power reactor Starfire. It is very important in such a toroidal system with interlinked components that all reactor components be easily accessible for repair, maintenance, and exchange. These requirements pose a serious engineering challenge. Many pertinent design studies for the exchange of reactor components exist, but no convincing solutions have been found. The problem is aggravated by the inaccessibility of the reactor hall, even after short reactor operation, because of radioactivity. All service and maintenance must be performed by remote control.

Construction Materials. Connected with the maintenance problem is the choice of materials for the reactor structure, the first wall, and other components inside the shield. Material requirements are resistance against radiation damage, compatibility with lithium, low neutron absorption cross-section, low long-time activation, low tritium permeation, and good thermal and mechanical properties up to 10^3 K. For experimental devices such as NET or ITER, stainless steels (AISI 316) are very likely to be selected. They have been optimized for fission power plants, but they may not be the best choice for fusion reactors because of the very different neutron spectrum in fusion. Additional material research, which should also include low-activation alloys (i.e., ferritic or austenitic stainless steels with reduced or replaced N, Ni, Mo, Cu, and Nb content; vanadium alloys such as V-15 Cr-5 Ti, V-20 Ti, V-3 Ti-1 Si), is necessary. Research should be devoted especially to understanding material properties when materials are exposed to large fluences of 14-MeV neutrons that are produced in the D – T reaction. Neutron irradiation affects the mechanical, thermal, and electrical properties of materials in many ways; it produces, for example, various defects in the crystal lattice by generation of recoil nuclei, and generates hydrogen and helium via (n, p) and (n, α) reactions. The most serious consequences, pertaining particularly to the first wall and other casings and containing systems (blanket elements, coolant pipes, etc.), are loss of ductility and swelling of the material. Radiation damage is especially critical for the first wall between the plasma and the blanket. Here the flux of primary fusion neutrons with a 14-MeV maximum will be at least $5\times10^{13} - 5\times10^{14}\,\mathrm{cm^{-2}\,s^{-1}}$ corresponding to a power density of 1 – 2 MW/m^2. Furthermore, the first wall is exposed to high fluxes of photons and high-energy ions and atoms that escape from magnetic confinement. By bombardment with fast plasma particles, wall material is sputtered off, leading eventually to contamination of the plasma and deterioration of the energy confinement.

The questions of radiation damage and first-wall durability are considered key problems in fusion reactor development, equivalent to the problem of plasma containment. Present expectations are that the first wall and the blanket will have to be replaced 3 to 4 times during the lifetime of a power reactor.

Inertial Confinement Fusion Reactors. System studies and conceptual designs on inertial confinement fusion reactors have also been performed. In a laser fusion reactor the pellets are placed in the center of a burn chamber, where thermonuclear burns are initiated by laser pulses. A blanket of lithium surrounds the chamber and the exploding pellets. The minimum energy release in one microexplosion, determined by physical and economic constraints, is about 100 MJ (equivalent to 20 kg of TNT). Because the energy is carried by a small mass of high-energy particles (neutrons, α particles, and pellet debris) and by radiation, control of the hydrodynamic blasts may be eased. To protect reactor components, designers have proposed lithium wetted-wall chambers, magnetically protected walls, and liquid lithium curtains. A performance map of the operational parameters for a 1-GW$_e$ power plant with a single reactor chamber is depicted in Figure 144. This figure shows the driver energy required, the fusion energy released per pulse and the repetition rate necessary to reach 1-GW$_e$, if the indicated performances i.e., energy gain in the pellet, and driver efficiency, could be achieved. Energy gain is the ratio of the driver energy absorbed in the pellet to the fusion energy released. According to Figure 144, a 1-GW$_e$ single- chamber power plant in the intermediate gain region (G $\approx$ 100 – 500) would require laser drivers of at least 10 – 20 % efficiency, with megajoules of driver energy and a repetition rate of $10^5 - 10^6$ pellets per day. Each pellet will produce only about 10 kW · h electrical energy. Pellet factories would have to be installed to produce the relatively complicated

Figure 143. Starfire commercial Tokamak reactor reference design, showing exchange of modules

multishell pellets cheaply, but with high precision. The development of efficient drivers, the mass production of pellets, the handling of about 0.5 kg of tritium per day, the design of blast-resistant chambers, and the safety aspects of repeated nuclear blasts in a surrounding of highly radioactive components pose extreme demands that must be met for energy production. These problems in combination with the relationship of ICF research to nuclear weapons development, may have led the EC to concentrate almost exclusively on magnetic confinement fusion.

6.3.2. Energy Resources and some Economic Aspects

Fusion reactors based on the D – T reaction consume lithium and deuterium as primary fuels. *Deuterium* is present in all water. With a supply of about 10^{13} t in the oceans and a specific consumption of about 25 g MW_{th}^{-1} a^{-1} in a fusion reactor, the equivalent energy resources of deuterium are practically unlimited. *Lithium* is widely distributed in the earth's crust. At present, it is extracted from brine and pegmatitic ores. At least about 1.2×10^6 t of lithium is economically minable from the land mass. This amount corresponds to an approximate total energy production of $3.5\times10^4 - 12.3\times10^4$ EJ (1 EJ = 10^{18} J), if it were used up in future fusion reactors. The average lithium content of seawater is about 0.1 ppm, leading to technically available resources of 10^{11} t, with an energy equivalent of 5×10^9 EJ. The total worldwide energy consumption in 1990 was about 350 EJ. Thus with respect to fuel supplies, fusion can be considered an inexhaustible energy source. Lithium and deuterium can be extracted from seawater relatively easily and at low cost. By using actual raw material prices for deuterium and lithium, specific fractional energy costs for fuel (D_2+ Li) of 3×10^{-3} cents/$kW_e\cdot h$ would result.

Figure 144. Operational parameters of an W_e 1-GW ICF power plant showing the driver energy and the fusion yield per pellet explosion and the repetition rate required for a single reaction chamber. Conservative and optimistic gain refer to assumptions in the implosion physics. η_d is the driver (photon- or ion-beam) efficiency.

The average energy density in a fusion reactor is very low (some watts per cubic centimeter). Thus, the energy expenditure to build a reactor might be too high, or the energy payback time could be too long. Extensive studies have shown that the *energy expenditure* to build and operate a 1-GW_e fusion reactor will be less than 1 % of the total net energy gained in 30 years of operation. This relation is more favorable for the fusion reactor than for a fission reactor (LWR) because of the low energy expenditure for fuel in the fusion reactor.

Cost estimates of generating electricity by fusion have been made. They are necessarily imprecise for a system that will not be put in general service until the middle of the next century, at the earliest. For a Tokamak reactor the costs of fuel and fuel processing are negligible, but the capital costs of the plant are high, particularly for the unconventional part– the Tokamak reactor. System studies made in 1977 – 1980 estimated the total capital costs for a commercial power plant with a Tokamak reactor to be between \$ 1280 and 1440/kW_e using prices at that time. Energy price projections have been made for the middle of the next century. At that time, energy costs for fusion-generated electricity should be comparable to those of fission reactors and coal power plants but should be still cheaper than those of photovoltaic electricity generation. Thus, from the present point of view, competitive production of electrical energy by nuclear fusion seems possible.

6.3.3. Environmental Impact and Safety-Related Aspects of Fusion Power

Although, presently, the fundamental principles of thermonuclear fusion deserve most of the research effort, several studies on the environmental impact of fusion power were performed in the 1990s. Quantitative statements on these safety and environmental properties of the future fusion reactor are based on the detailed design of a 1 GW_e Tokamak reactor of the FCTR type (European First Commercial Tokamak Reactor).

As a result of these investigations the following favorable statements with respect to the safety and environmetal impacts of the fusion reactor can be made:

1) In a fusion reactor chain reactions and steep power excursions – which would result in a power runaway of the reactor – do not occur.
2) The radioactive materials in a fusion reactor – tritium and the activated material produced by activation of the reactor structure by fusion neutrons – have a relatively low biological hazard potential.
3) The quantity and the activity of the radioactive materials produced in a fusion reactor will be substantially reduced by future material developments.
4) The acquisition of materials for fusion reactors will not despoil their resources. The fusion fuels deuterium and lithium (which serves as breeding material for tritium) are abundant and widely distributed on earth. Exceptions may be beryllium and helium for specific reactor designs, since beryllium may be used as a neutron multiplicator in blanket designs with solid breeders, and helium is needed for the superconducting coils.
5) Fusion reactors do not emit chemicals that might have an impact on the climate.

Environmental Impact. The biological hazard potential of tritium, a β emitter with a half-life of 12.3 a, is relatively low. Nevertheless, protection of the environment from the radiological impact of a fusion power plant depends essentially on the control of tritium emission. Tritium can penetrate hot metallic walls relatively easily. In reactor design, extensive measures for tritium containment must be employed, such as doublewalled tubing, diffusion barriers, low tritium concentration in coolant pipes, detritating of the reactor hall, and outer metallic containment for both the reactor hall and the tritium process building. Provided that leakage is limited by such measures, estimates forecast that tritium losses and their effects can be made smaller than required by current radiological safety regulations. For the FCTR (1.2 GW_e) a release of 2 g of tritium per year (740×10^{12} Bq/a) of atmospheric emissions and 0.15 g of tritium per year (50×10^{12} Bq/a) of aquatic emissions are estimated. These emissions occur mainly because of maintenance work. If it is unfavorably assumed that all emissions are in their oxidized form (HTO; an unfavorable assumption), a person living at the reactor fence (1000-m distance) would obtain a dose of 8 µSv/a (0.8 mrem/a), provided that dilution caused by a chimney or by cooling water is taken into account. In planning nuclear power stations, a dose of < 300 µSv/a must be guaranteed.

In Tokamak reactor designs with stainless steel as the structure material the *radioactive inventory* formed by neutron activation is very high. Its activity (FCTR: ca. 2.8×10^{20} Bq/GW_e) is comparable to that of fission reactors. Most of the activity is found in solid metallic structural components, with no actinides, no plutonium, and not many volatile radioactive materials in addition to tritium.

In routine reactor operation, activated structural materials will be released to the environment only in negligible quantities, mainly as corrosion products. The biological hazard potential (BHP) of a fusion reactor is considerably lower (10 – 100-fold) than that of fission reactors and decays much faster after shutdown.

Furthermore, the BHP depends on the structural materials of the reactor. In current designs, reactor steels are foreseen. The BHP could possibly be reduced further by radiologically tailoring the materials used in construction of the plant, (i.e., choosing low-activation materials that form no long-lived isotopes). Different alloys (e.g., steels without nickel and molybdenum, or vanadium – titanium alloys) have been proposed with which the decay time of radioactivity is drastically reduced and a considerably lower total BHP results.

Radioactive Waste. Assessments indicate that Tokamak fusion reactors produce huge amounts of radioactive waste during their lifetimes. Such waste is caused mainly by maintenance; by first-wall and divertor plate erosion by replacement of the first wall; of plasma facing components, and of the breeding blanket. The high-activity waste stems mainly from the stainless steel structure of the first wall. It must be disposed of in geologic repositories. Indications are that the high- and low-activity wastes are comparable in volume and initial activity to those of a fission reactor with the same power output. The low-activity waste comes mainly from the tritium handling and purification systems, and probably also from solid breeder materials. Again, the possibility exists for developing materials with favorable radiological properties, so that part of the waste may even be recycled after a sufficiently long cooling time.

Reactor Accidents. With respect to accidents during operation and accidental release of *radioactivity*, precise statements cannot be made because fusion reactor designs are still in the planning stage and credible accidents cannot be identified or evaluated very well. Maximum consequences can only be roughly estimated. The reaction chamber in a fusion reactor contains a small amount of fuel, sufficient for some seconds of burn time. The reaction rate is self-limiting, so a power excursion is impossible. Furthermore, the power density of the decay heat and its increase after shutdown of a fusion reactor are much lower than in a fission reactor. Thus, emergency cooling is considerably easier in fusion reactors, and meltdown of materials can be excluded. The energies stored in the reactor components are not high enough to melt or evaporate a considerable fraction of structural material.

Most of the hazard could be expected from the *chemical energy* of the metallic lithium

in the blanket in the event of a lithium fire. Lithium reacts vigorously with air, water (self-ignition), and even concrete. Radioactivity cannot be induced in lithium. In modern reactor designs, breeding blankets are provided that contain solid lithium compounds or lithium – lead alloys. Such materials are not prone to exothermic reactions or self-ignition.

A potential environmental hazard in the event of accident is primarily the *release of tritium*. Even in severe accidents, only up to 200 g tritium is expected to be released into the reactor hall or other buildings because most of the tritium inventory ($\approx$ 5 kg) is rigidly bound in reactor structures in the storage and partially in the process systems, all of which are in different isolated buildings. The release outside the buildings may be kept one or two orders of magnitude lower than the release inside, given the outer containment and tritium removal in the reactor buildings by emergency cleanup systems. Even in an accident that ruptures the building containment (earthquake, airplane crash, sabotage), only the tritium content of the pertinent building (about 100 g) is expected to be released to the environment.

Estimates of *radiation exposure* (*effective dose*) have been made, based on a release of 10 g of tritium as HTO. The effective dose for adults living within 1000-m distance and consuming permanently contaminated food would be about 25 mSv (2.5 rem). According to radiological safety regulations, the limiting dose in accidental radiation exposition (abnormal events of very low probability) is 5 – 15 rem.

In relevant contemporary studies, no sequence of events could be identified in any accident scenarios for considerably higher releases of radiation. Nevertheless, in the extreme limit, hypothetical release of the total mobilizable inventory of about 1.5 kg of tritium and 1 kg of activated structural material may be contemplated. Even then, evacuation would not be required beyond a radius of a few kilometers, if the limits for evacuation are 5 – 25 rem. Therefore, fusion is not expected to cause a major disruption of normal life in the community surrounding the reactor site.

1. Introduction

Nucleic acids are high molecular mass compounds found in all living cells and viruses. Their name originates from their discovery in the nuclei of eucaryotic cells. They can be chemically degraded to yield phosphoric acid, pentoses, and nitrogen-containing heterocycles (bases). Nucleic acids can be divided into two main classes depending on the sugar they contain: *deoxyribonucleic acids* (DNA) contain 2-deoxy-D-ribose and *ribonucleic acids* (RNA) contain D-ribose.

Nucleic acids are long, unbranched chains of sugar and phosphate (Fig. 1, see next page): the C-3′ atom of each sugar is linked by a phosphodiester bond to the C-5′ atom of the neighboring sugar. Either a purine (adenine, guanine) or a pyrimidine (cytosine and thymine in DNA; cytosine and uracil in RNA) is attached to C-1′ of the sugar by a β-glycosidic bond. For a detailed description of purines and pyrimidines, see → Purine Derivatives, → Pyrimidine and Pyrimidine Derivatives.

Although nucleic acids have been known since the second half of the nineteenth century it was only in the 1940s that their importance as the carrier of genetic information became clear. Genetic engineering and improved physical and biochemical methods of analysis have led to enormous progress in the understanding of the structure of DNA, DNA – protein interactions, and gene organization, expression, regulation, and transfer. The importance of nucleic acids became even more obvious after the discovery that they can have other functions in addition to their ability to store and transfer genetic information. It is widely assumed that in the course

10.1002/14356007.a18_001

of evolution first RNA and then DNA came into being [36, 37].

Figure 1. Structure of DNA (R = H) and RNA (R = OH)
B = base (adenine, guanine, thymine or uracil, cytosine)

2. Structure

2.1. Structure of DNA

The joining of the DNA building blocks by 5′- and 3′-phosphodiester bonds gives the molecule polarity (Fig. 1); base sequences are always written starting with the 5′-terminus, i.e., in the $5' \rightarrow 3'$ direction. The specific base sequence of DNA and its ability to form double-stranded structures according to precisely defined rules are of utmost importance for the storage of genetic information and for interactions with other nucleic acids and proteins.

From X-ray analysis data, Crick and Watson proposed a double-stranded structure for DNA in 1953 in which two antiparallel (i.e., $5' \rightarrow 3'$ and $3' \rightarrow 5'$) polynucleotide chains form a right-handed helix (i.e., looking along the axis of the helix, the strands are coiled clockwise). Naturally occurring DNA usually consists of right-handed helices with a major and a minor groove (Fig. 2). The hydrophobic bases are located inside the helix and the sugar – phosphate "backbone" on the outside [38]. Bases that are opposite each other are paired according to defined rules as a result of hydrogen bond formation: adenine always pairs with thymine or uracil and guanine with cytosine. Complementary bases can be bound by the more common Watson – Crick pairing (Fig. 3 A) or by Hoogsteen base pairing (Fig. 3 B). The double-stranded structure is further stabilized by hydration of the phosphate groups and hydrophobic interactions between the aromatic ring systems that result in stacking of the bases.

Figure 2. Right-handed double-helix of DNA
A = adenine, C = cytosine, G = guanine, T = thymine

In double-stranded DNA, the bases are densely stacked and there is a cooperative effect between hydrogen bonding and stacking. Internal bases can be continuously paired and unpaired; double-stranded regions open and form single-stranded "bubbles" ("breathing" of DNA). Breathing is more frequent in regions rich in A – T pairs and could be important for interactions with proteins. DNA helices can exist in various forms (A, B, C, D, and Z) [39] some of which are interconvertible depending on the concentration and type of salts present. The helices always exhibit a degree of microheterogeneity that plays an important part in genetic regulation mechanisms.

The DNA helices can exist in linear form (e.g., in the chromosomes of higher organisms)

Figure 3. Watson – Crick base-pairs (A), and Hoogsteen base-pairs (B)

or as closed rings (e.g., in *Escherichia coli*); the molecules can also be twisted (superhelicity or supercoiling). In order to accommodate the large amount of DNA present in living cells, it must be packaged as compactly as possible with the help of proteins and RNA. Proteins can recognize specific binding sites on the DNA. The grooves of the DNA helix are large enough to allow proteins to come into contact with the bases [40]. Defined regions in DNA can also be recognized with the help of the methylation pattern of the bases (see Section 4.3).

Forms of DNA.

A-DNA can be observed in X-ray analyses at 66 % relative humidity. It has 11 base pairs per turn of the helix, the planes of the base pairs are tilted away from the vertical helical axis (19°), the helix is right-handed and has a diameter of ca. 2.3 nm.

B-DNA is the classical Watson – Crick form. It represents the structure of DNA at a relative humidity of > 92 % and largely corresponds to that found under physiological conditions. The helix is also right-handed with about 10.2 – 10.4 base pairs per turn and a diameter of ca. 2 nm. Single unpaired bases can be "looped out" of the helix and barely disturb the rest of the structure [41,42]. Protein – DNA interactions usually require recognition of nucleotide sequences in the major groove of the B-DNA double helix.

C-DNA helices can be observed at a relative humidity of 44 – 66 % in the presence of lithium salts. The helix is also right-handed and similar to the B form, but with 9.3 base pairs per turn.

D-DNA occurs in nature only in sequences with alternating adenine and thymine residues and in the DNA of the bacteriophage T 2 (T-DNA). The helix is also right-handed and has 8 base pairs per turn.

The left-handed conformation of *Z-DNA* has an alternating sequence of pyrimidines and purines and is formed in vitro at high salt concentrations (> 2 mol/L NaCl) or in the presence of divalent cations (Mg^{2+} > 0.7 mol/L). Unlike the right-handed helices (which have two grooves), this structure forms a single, very deep groove that penetrates the helix axis. The sugar – phosphate backbone assumes a zig-zag arrangement (therefore Z-DNA) with 12 base pairs per turn of the helix. Z-helices can form in vivo at physiological salt concentrations. They are less stable than B-DNA, but are stabilized by supercoiling, proteins, special ions, and methylation [43]. Torsional stress of DNA in vivo can favor the formation of Z-DNA [44]. Z-DNA and B-DNA are interconvertible; part of a DNA molecule may exist in the B form and another part in the Z form.

Supercoiling. Circular DNA and DNA between fixed sites can be twisted to supercoils. The term *supercoiling* refers to the curvature of the double helix axis. Supercoiled (superhelical) DNA was discovered in the 1960s in polyoma virus [45]. Rotation in the direction of winding is called *positive supercoiling* and rotation in the opposite direction is called *negative supercoiling*.

Torsional stress due to negative supercoiling can be overcome by the formation of DNA structures other than the B form. Negative supercoiling is a strong driving force for the stabilization of Z-DNA. Supercoiling makes DNA more compact, which is very important in DNA packaging. Almost all naturally occurring superhelical DNAs are underwound (i.e., have negative superhelices) but overwound DNAs also exist [46]. The strain produced by over- or underwinding can be accommodated by the formation of local single-stranded regions which tends to increase with increasing temperature. "Breathing" of the DNA (see third paragraph in Section 2.1) plays an important part here too. A sequence with $> 90\,\%$ A – T can exist permanently unpaired in a superhelical molecule. This is important for many reactions of DNA. Supercoiling influences transcription (see Section) and vice versa. Positive supercoils are formed in front of the transcription apparatus and negative supercoils behind it; these supercoils are controlled by enzymes [47].

Bending. The base sequence of DNA is of tremendous importance for its structure [44]. In a right-handed helix, the twist angle between two bases changes depending on the sequence. This may result in the bending of a linear double helix. Bending can also be caused by proteins. Bending is of significance for the packaging of DNA and for many of its biological reactions [48, 49].

Intrinsically bent DNA is formed when special base sequences or structural motives are repeated in phase with the DNA helical repeat; homopolymeric A tracts being the best example [50, 51]. Protein-induced DNA bending plays an important role in recombination, initiation of transcription, and replication [52, 53]. Bends are also important structural features; indeed, regulatory protein binding sites can be replaced by an intrinsic bend [49, 54].

Special Structural Elements. Short sequences are frequently repeated in regulatory regions. *Repeats* can be recognized by DNA-binding proteins. Owing to DNA breathing, double-stranded regions (hairpins or stem-loops and cruciform structures) can be formed at repeats within a single strand (Fig. 4). This rarely happens in double-stranded DNA because stem loops are energetically less favorable than linear double strands. However, it is encountered frequently in single-stranded DNA and RNA. Supercoiling can promote the formation of cruciform structures, whereas transcription inhibits it [55]. Hairpins can play a part in replication, transcription, and RNA processing [56].

Figure 4. Special structural elements in nucleic acids

Homopyrimidine – homopurine runs are frequently found in regulatory regions of eucaryotic genes and are especially sensitive to nucleases [57]. There is a high tendency to form right-handed structures other than B-DNA in such regions [58].

Although the chains of double-stranded DNA are normally antiparallel, *parallel double-stranded oligomers* have also been found in vitro [59]. They form a right-handed helix and are even recognized by several enzymes. They are less temperature-stable than the corresponding oligomers.

At homopurine – homopyrimidine sections of the DNA, a homopyrimidine oligonucleotide can attach itself parallel to the homopurine strand in the major groove and form a *triple helix* [58]. Structures of this type can be used for specific strand cleavage with the help of coupled ellipticine derivatives or metal chelates [60, 61].

Centromeres are important compact DNA structures of the eucaryotic chromosome that are rich in adenine and thymine. Their exact structure is not known but they are important for the attachment of the spindle fibers during mitosis.

The ends (*telomeres*) of linear chromosomes (as in eucaryotic DNA) pose a special problem. DNA polymerases synthesize DNA from a DNA template and always require an RNA primer to start replication. Cleavage of this primer then results in a small 5′-gap which cannot be closed by the polymerase. Under normal replication conditions, the ends should therefore beocme shorter with every cycle of DNA replication (see Section 4.1). Special enzymes (telomerases) are responsible for adding telomere repeats to the chromosome ends to maintain constant length (Fig. 5): repeats can fold back and provide a 3′-OH group which serves as a primer for copying the last segment of a linear DNA molecule. Disturbances in telomeres can lead to aging phenomena [62, 63] and a role in carcinogenesis is also being discussed. Broken ends of chromosomes that are no longer protected by telomeres are very susceptible to fusion with other DNA ends and to degradation by nucleases [64]. The antiparallel structure and function of telomeres are highly conserved in all eucaryotes and are species specific. They consist of simple, tandemly repeated sequences with clusters of G residues [65, 66]. The G-rich strand is aligned in the 5′ → 3′ direction towards the end of the chromosome and has a single-stranded 3′-end containing 12 – 16 nucleotides. Telomeres can associate to form stable, parallel, four-stranded structures (G 4-DNA) [67].

Figure 5. The importance of telomeres
Without telomere addition (A) newly synthesized DNA strands become shorter; with telomere addition by telomerase (B) constant length can be maintained.

2.2. Structure of RNA

RNA is an unbranched single-stranded polymer with many intramolecular double-stranded sections that may account for 50 – 67 % of the molecule. As in DNA, the backbone of RNA consists of 3′,5′-phosphodiester bonds (Fig. 1); however the sugar is ribose (and not deoxyribose) and uracil replaces thymine. Double-stranded RNA cannot form a B-helix because of steric hindrance caused by the 2′-OH groups of ribose; helices of the A type are, however, possible.

The functional groups of the nucleotides in the major groove of the A type of double he-

lix found in RNA are not easily accessible to proteins [68]. Protein binding to RNA probably occurs via interaction with single-stranded regions.

Four functional RNA families exist: messenger RNA (mRNA), ribosomal RNA (rRNA), transfer RNA (tRNA), and small nuclear RNA (only in eucaryotes). The structure of tRNAs has been studied most extensively; about half of the ca. 75 – 90 nucleotides within the tRNA molecule are paired, resulting in a secondary structure with a stem and three loops similar to that of a cloverleaf [69].

RNA has many different biological functions and exhibits a spectrum of flexible structures that more closely resemble those of proteins rather than those of the chemically related DNA [70]. RNAs have secondary structures–double-stranded sections, hairpins, internal loops, and bulged bases. With unpaired nucleotides pronounced tertiary structures are formed in addition to the secondary structure. Examples of tertiary structure motives are pseudo knots [71], produced by folding back in a hairpin and formation of a second stem – loop structure [72].

Formation of DNA – RNA hybrids is of importance in the replication and transcription of DNA and in the reverse transcription of viral RNA. Such hybrids can form secondary structures but they are considerably more polymorphous than DNA alone [73].

3. Properties

3.1. Physical and Chemical Properties

The size of naturally occurring DNA varies from a few thousand to 10^9 base pairs. The length of such molecules (micro- to centimeter range) can easily be measured under the electron microscope.

DNA absorbs UV light at 260 – 280 nm due to its bases. Aqueous DNA solutions are very viscous; viscosity depends on DNA length, DNA concentration, and temperature. Heating to a critical temperature is accompanied by a decrease in viscosity because the hydrogen bonds responsible for base pairing are disrupted and the helix structure collapses. This process is called *thermal denaturation or melting of DNA*. The temperature at which one-half of the base pairs is disrupted is denoted the *melting temperature*. It depends on the base composition (G – C pairs are more stable than A – T pairs). Double-stranded DNA ranging in size from 100 to > 100 000 base pairs melts at ca. 90 °C. In shorter double strands a gradual decrease in the melting temperature is observed. The melting temperature increases with increasing salt concentrations because the solubility of the bases decreases and hydrophobic interactions are increased. Chemicals that compete with hydrogen bond formation, such as urea or formamide, lower the melting temperature of DNA. Methanol has a similar effect; it increases the solubility of the bases and increases the interaction with water. The "melting" of double-stranded DNA is also facilitated by solvents such as ethylene glycol, dimethylformamide, dimethyl sulfoxide; low ionic strength; or extreme pH values. DNA can be denatured at an alkaline pH because the keto – enol equilibria of the bases are shifted preventing these groups from participating in hydrogen bonding.

Since the stacked bases in the double-stranded helix are not as easily excited by UV light as in single strands, absorption at 260 nm is lower for double-stranded DNA than for single strands. Increase in UV absorption can thus be used to measure DNA denaturation. At 260 nm solutions containing 50 µg/mL of double-stranded DNA, 50 µg/mL of single-stranded DNA, and 50 µg/mL of free bases have absorptions of ca. 1.00, 1.37, and 1.60, respectively.

Denaturation can also occur in the presence of proteins that destabilize the helix (melting proteins). Such proteins are required to unwind the helix during replication and to facilitate interaction between single strands during genetic recombination.

The reassociation (renaturation) of thermally denatured DNA is a spontaneous process but only occurs if the solution is cooled slowly below the melting temperature. Renaturation can take several hours, depending on the size of the molecule, because it initially relies on random base pairing (hybridization); it is, however, a cooperative process. Rapid cooling of denatured DNA at salt concentrations > 50 mmol/L produces a very compact molecule in which about two-thirds of the bases are hydrogen bonded or stacked. At salt concentrations below

10 mmol/L the DNA remains denatured even after cooling.

The length of RNA varies greatly: tRNA has a length of 75 – 90 nucleotides and mRNA can be up to several thousand nucleotides long. Denaturation effects are rarely observed because RNA has few truely double-stranded regions; it is most likely to be observed in tRNA.

Because they are extremely long, DNA molecules are extremely sensitive to mechanical influences (shearing forces, e.g., vigorous stirring) and easily break into small fragments (ca. 1000 base pairs). Ultrasonic treatment of DNA in solution produces fragments of ca. 100 – 500 base pairs owing to disruption of hydrogen bonds and single-strand and double-strand breaks in the sugar – phosphate backbone [74]. Nucleic acids are sparingly soluble in water (depending on the molecular mass). They are negatively charged and acidic at physiological pH and form water-soluble alkali and ammonium salts that can be precipitated with ethanol.

RNA and DNA are insoluble in cold acid. DNA is more sensitive to acid hydrolysis than RNA. At pH < 1, however, both DNA and RNA break down into the free bases, phosphoric acid, and (deoxy)ribose. Acid hydrolysis can be used to determine the base composition of nucleic acids (e.g., total hydrolysis can be achieved by heating DNA in 90 % formic acid at 180 °C for 30 min). The β-glycosidic linkage between the N-9 of purines and the C-1 of deoxyribose is selectively cleaved at ca. pH 4, resulting in apurinic sites. Anhydrous hydrazine cleaves the pyrimidine residues.

DNA is stable at pH 13, only 0.2 of 10^6 phosphodiester bonds are broken per minute at 37 °C. In contrast, RNA is rapidly hydrolyzed at alkaline pH.

DNA can be both specifically and nonspecifically cleaved by a variety of enzymes [deoxyribonucleases (DNases)]. RNA is cleaved by ribonucleases (RNases). Some of these cleavage reactions are exploited for sequencing RNA [75, 76]. See also → Enzymes, Chap. 6.4.→ Enzymes, Chap. 6.5.

3.2. Interaction with Proteins

In bacteria, DNA occurs as a complex with RNA and proteins that is bound to but not surrounded by a membrane. The DNA often has a closed circular form and is organized in a series of superhelical loops.

The DNA of higher cells is enclosed within the nuclear membrane as morphologically distinct units of varying size (chromosomes); it is associated with basic proteins called histones. The number and size of the chromosomes are species specific (karyotype). Two full turns of the DNA double helix (146 base pairs) are wound around a histone octamer (diameter ca. 8.6 nm) to form a nucleosome. The width of the grooves varies due to the periodic arrangement of A – T trinucleotides on the inside and G – C trinucleotides on the outside of the nucleosome at intervals of about ten base pairs [53]. Nucleosomes can become condensed into fibers of 10 or 30 nm (super superhelices, solenoids).

Eucaryotic cellular organelles (e.g., mitochondria, chloroplasts) possess closed circular DNA that is not associated with histones.

4. Biosynthesis and Biological Function

4.1. DNA Replication

The genetic information of all cellular organisms is stored in double-stranded DNA (viruses may, however, also have single-stranded DNA or RNA, as well as double-stranded RNA). It is extremely important that the transfer of biological information in DNA (i.e., its base sequence) occurs with a very high degree of accuracy. Because of perfected proofreading and repair mechanisms (see Section 4.5) DNA replication has an error level of $10^{-8} - 10^{-11}$ [77], i.e., for every $10^8 - 10^{11}$ bases in newly synthesized DNA only one is incorrectly incorporated. The replication of DNA is carried out by DNA polymerases which require a single strand of DNA as a template and a short double-stranded piece of nucleic acid (formed with the help of a primer) for initiation (Fig. 6; see also → Enzymes, Chap. 6.2.).

The DNA is synthesized from deoxyribonucleotide triphosphates which are polymerized on the single-stranded DNA template with the release of pyrophosphate; the cleavage of pyrophosphate by a pyrophosphatase provides the

energy required for DNA biosynthesis. The addition of new nucleotides always takes place at the 3′-OH group of the sugar, therefore all biologically synthesized nucleic acids grow in the $5' \rightarrow 3'$ direction. Divalent cations such as Mg^{2+} or Mn^{2+} are important cofactors. Some polymerases contain $3' \rightarrow 5'$ exonuclease activity and can remove bases that have been incorrectly incorporated. The primer in vivo is usually RNA, which is synthesized by a special RNA polymerase (primase) and removed later by an exonuclease (e.g., DNA polymerase with $5' \rightarrow 3'$ exonuclease activity). The various activities are combined in a multienzyme complex.

Figure 6. Simplified scheme of DNA replication
A) Lagging strand synthesis: after primer addition by primase a stretch of DNA is synthesized by DNA polymerase, the primer is removed and after synthesis of the adjacent stretch of DNA the phosphodiester bond between the two stretches is closed by a DNA ligase.
B) Leading strand synthesis: after primer addition by primase the new strand is synthesized by DNA polymerase. Arrows denote direction of synthesis.

The replication of DNA is a semiconservative process, i.e., one strand of each of the two new daughter molecules of DNA is an old strand and the other a newly synthesized one [78]. Replication starts with the creation of replication forks at the "origin of replication", and proceeds in opposite directions along the DNA (see Fig. 6).

The DNA of procaryotes is replicated from a single replication origin. The main replication enzyme in *Escherichia coli*, DNA polymerase III, consists of at least ten different subunits. Replication is probably a membrane-bound process [79].

Because DNA strands are antiparallel, one strand (lagging strand) must be synthesized "backwards" to keep the replication complex together. The direction of synthesis of this strand is contrary to the direction of movement of the replication fork and occurs discontinuously. Segments (Okazaki fragments) are formed which are then joined by a DNA ligase. The strand, that is synthesized "forward" is called the leading strand. Replication in eucaryotes starts at several points along the DNA and the replication complexes are fixed to the nuclear matrix [80]. Viroids are the smallest self-replicating structures known. These single-stranded, circular, protein-free RNAs are a few hundred nucleotides long and occur as pathogens in higher plants [81].

4.2. Gene Expression

The base sequence of DNA constitutes the genetic information in the form of discrete units (genes). A sequence of three successive bases (codon) acts as a code for a certain amino acid (e.g., GCT, GCC, GCA, or GCG code for alanine) or as a stop signal (TAG, TGA, or TAA) in protein synthesis. Of the 64 ($=4^3$) possible triplets, 61 code for amino acids and 3 specify stop signals. Since this genetic code is almost universal, eucaryotic proteins can be synthesized in procaryotes from eucaryotic DNA (→ Genetic Engineering). Some organisms and organelles differ in a few codons from the universal code [82]. The genetic information contained in DNA is normally used as a template for the synthesis of mRNA which itself then acts as a template for protein synthesis.

The regulation of gene expression in living organisms is based primarily on the recognition of nucleic acid sequences by proteins. However, nucleic acids can also be involved. "Antisense RNA" for instance, can hybridize with mRNA, leading to a block of translation and to the degradation of the mRNA by RNase. The termination of transcription can occur in a similar way. This principle may possibly be exploited for therapeutic applications [83].

4.2.1. Transcription

The process by which genetic information is transferred from DNA to mRNA is called transcription. This process is catalyzed by DNA-dependent RNA polymerases and involves the synthesis of mRNA from ribonucleotide triphosphates in the presence of Mg^{2+} or Mn^{2+} and a single- or double-stranded DNA template. The direction of synthesis is $5' \rightarrow 3'$ and no primer is required. As in DNA synthesis, energy is obtained from the cleavage of pyrophosphate. The accuracy of transcription is lower than that of DNA replication (ca. 10^{-4}) because there are no repair processes [77]. Most RNA polymerases are complex enzymes consisting of several subunits. Bacteria generally have one, but eucaryotes have three (see also → Enzymes, Chap. 6.3.).

Due to the specific base pairing in the double strand, the base sequence information of DNA determines the base sequence of the mRNA synthesized by RNA polymerases. Messenger RNA acts as an intermediate for conveying the information required for protein synthesis from the DNA to the protein-synthesizing structures, i.e., the ribosomes (see below). For interaction with the ribosome, mRNA possesses a ribosomal binding site shortly before the translation initiation sequence. This site is complementary to rRNA sequences [84]. The average length of *Escherichia coli* mRNA is about 1200 base pairs, eucaryotic mRNA can be much longer. Some types of mRNA are very rapidly degraded and exist in relatively low concentrations. Other types are more stable and accumulate in considerable amounts in the cell. The ends of mRNA are important for its stability.

Modifications in the form of loop structures [85] in procaryotes, and poly(A) at the $3'$-terminus and a cap (formed by addition of 7-methyl-GTP followed by methylation) at the $5'$-terminus in eucaryotes protect the ends from nonspecific degradation by nucleases (Fig. 7). Capping and the addition of poly(A) usually occur before splicing. Random degradation of mRNA is also prevented by cellular ribonuclease inhibitors. The mRNA transcript is finally exported to the cytoplasm where it acts as a template for protein synthesis.

Transcription is increased or decreased by sequence elements on the DNA that act as binding sites for protein factors [86–88]. Transcription also involves initiation and termination factors, some of which are ribonucleoproteins. Structural features also affect transcription, e.g., bent DNA can activate the process [52].

Figure 7. Simplified scheme of transcription in eucaryotes A DNA template is transcribed into pre-mRNA by RNA polymerase (A) and a cap is added to the $5'$-end of the mRNA (B). A stretch of A-residues is then added to the $3'$-end. During splicing intervening sequences (introns) are removed and the sequences carrying the information for protein synthesis (exons) are joined to form mature mRNA (C).

RNA polymerase binds to a promoter region in the DNA template and then transcribes the DNA into mRNA. In most eucaryotic genes protein-coding sequences (exons) are interrupted by intervening noncoding sequences (introns). Many exons code for protein domains; exon rearrangements in DNA can facilitate the exchange of domains (exon shuffling). Lower eucaryotes have a higher content of intron-free genes than higher eucaryotes. Introns are rarely found in bacterial genes [89]. Introns are removed from eucaryotic precursor mRNA and the exons are then joined to give mature mRNA in a process known as splicing (see Fig. 7). The length of introns varies from 30 to 100 000 base pairs, the average exon length is 50 – 300 base pairs. Splicing demands a high degree of accuracy and is carried out by a multicomponent

complex known as a spliceosome that consists of protein and small RNAs (snRNAs = small nuclear RNAs). The main components of the spliceosome are ribonucleoproteins (snRNPs = small nuclear ribonucleoproteins) [90, 91]. Introns usually start with GU (5′-splice site) and end with a pyrimidine-rich section followed by AG (3′-splice site) [92]. The half-life of introns in mRNA varies from a few seconds to 10–20 min. Splicing always takes place in the nucleus. Unspliced RNA remains in the nucleus and is degraded.

The splicing mechanism is highly conserved: a mammalian cell extract can process yeast RNA. The number of possible transcription products can be increased by alternative splicing (i.e., not all available exons of a gene are used to create one mature mRNA).

In protozoa RNA is also "edited", the primary transcript is converted into its functional form not only by post-transcriptional removal of certain bases, but also by insertion of others [93, 94].

In some RNA viruses (retroviruses), replication of the genetic material proceeds via a DNA intermediate in a process known as reverse transcription. The information in RNA is transcribed back to DNA with suitable enzymes (reverse transcriptases). The DNA is then used as a template for RNA synthesis (see also → Enzymes, Chap. 6.2.4.). Reverse transcription can also be used in vitro to produce intron-free complementary DNA (cDNA) from eucaryotic mature mRNA. Telomerases are special reverse transcriptases with an internal RNA template [95, 96].

4.2.2. Translation

Protein synthesis takes place on the ribosomes, which are complexes of rRNAs and more than 50 different proteins. Protein factors are involved in all phases of translation. Various types of RNA are involved in protein synthesis: mRNA, the carrier of genetic information from the DNA; rRNA, component of ribosomes and directly involved in almost all stages of protein synthesis [97]; and tRNA, which makes activated amino acids available for protein synthesis. Translation is an irreversible process with error rates of 10^{-3} – 10^{-4} [77].

The initiation of protein synthesis is a very intricate multistep process [98, 99]. A translation initiation complex is formed from ribosomes, mRNA, a special tRNA, initiation factors, and GTP. The mRNA start codon for protein biosynthesis is usually AUG but GUG, UUG, or AUU may also be used [89]. After initiation of translation, the protein is synthesized step by step (elongation) from amino acids that are delivered and activated by tRNA. Each amino acid has a specific tRNA.

The tRNAs act as adapters between the codons of mRNA and the corresponding amino acids. Apart from the "usual" bases, tRNA contains several rare bases (e.g., 5-hydroxymethylcytosine). Transfer RNAs have an amino acid attachment site and a template recognition site (anticodon) for the mRNA. Amino acids are attached by an ester bond either to the 3′-or 2′-OH group of the terminal adenosine of tRNAs. Loading the tRNAs with the correct amino acids is crucial for exact translation of genetic information. This step is catalyzed by specific enzymes (aminoacyl-tRNA synthetases). Each of these enzymes must be able to recognize a specific amino acid and its associated tRNA.

The amino acid sequence of the protein product is specified by the mRNA codons and thus ultimately by the base sequence of DNA. A stop codon (TAA, TAG, TGA) on the mRNA leads to termination of protein synthesis and the release of the protein. Differences between translation complexes in procaryotes and eucaryotes permit the selective interruption of procaryotic protein synthesis (e.g., by some antibiotics).

4.3. Modification and Degradation

DNA is exposed to many damaging influences and can be modified and cross-linked by radiation and chemicals. Spontaneous hydrolysis of DNA bases may also occur.

Mutations change the normal base sequence of DNA. Erroneous bases can appear as a result of replication errors or chemical modification (→ Mutagenic Agents). Intercalating agents such as benzopyrenes, aflatoxins, or ethidium bromide can cause deletions. Insertion of individual bases is also possible. Insertion of larger DNA segments can occur through mobile DNA elements (transposable elements, jumping

genes). The insertion site is usually arbitrary. This process (transposition) can lead to gene activation or inactivation.

Methylation of DNA is used by cells in different ways [100, 101], e.g., to distinguish between newly synthesized strands (unmethylated) and old strands (methylated). Methylation occurs at defined sites: in bacteria at the N-6 position of adenosine and the C-5 position of cytosine, and in eucaryotes, physiologically only at cytosine. The methylation pattern also differentiates between endogenous and foreign DNA and is recognized by restriction – modification systems (in procaryotes): endogenous DNA is methylated at specific sites and foreign DNA is digested. Methylation can be used to switch genes on or off in eucaryotes. C-Methylation influences the equilibrium between B- and Z-DNA [102] and can lead to altered DNA – protein interactions by the modulation of DNA topology. Methylation patterns are stable and hereditary. Methylation can have a mutagenic effect: the deamination of 5-methylcytidine to thymine occurs spontaneously.

Degradation of nucleic acids can be effected in vivo and in vitro by a series of enzymes. Some DNases are specific for single strands and others for double strands, some cleave bonds located within a double strand (endonucleases) and others require a free DNA end (exonucleases). Exonucleases act either in the $3' \rightarrow 5'$ or the $5' \rightarrow 3'$ direction; exonuclease activity is often associated with DNA polymerases for proofreading in DNA replication. Restriction endonucleases are a special class of nucleases. RNases can also be divided into exo- and endonucleases. RNase II is a bacterial exonuclease; RNase H is an endonuclease that digests RNA in DNA – RNA hybrids. See also, → Enzymes, Chap. 6.

4.4. Recombination

In recombination two DNA molecules interact and exchange segments to produce two new molecules that contain genetic information from both parental DNAs. DNA recombination is by no means limited to genetic engineering, but occurs widely in nature. This process is catalyzed by enzymes and usually requires the presence of homologous regions (homologous recombination). In rarer cases, nonhomologous, illegitimate recombination can take place. Transposition (see Section 4.3) is also a recombination phenomenon [103].

4.5. DNA Repair

Although changes in base sequences create the genetic variety required for evolution, these changes are only rarely beneficial for individual organisms. Despite many damaging influences (see Section 4.3), nucleic acids are replicated with amazing accuracy. This exact conservation of genetic material is one of the fundamental requirements for genetic success. Damaged DNA that is not repaired can lead to mutations and cell death, and give rise to tumors. Living organisms have therefore developed a variety of enzymatic mechanisms for eliminating DNA damage. Most damage is recognized by repair systems in the cell and repaired either by directly reversing the damage or by using the undamaged second strand as a template. *Escherichia coli* has been used as a model for studying repair mechanisms [104]. The best studied mechanism is nucleotide excision repair. This multistep process involves recognition of the error, nicking of the damaged strand, removal of nucleotides at the damaged site, repair DNA synthesis, and ligation. It requires the participation of multienzyme complexes [105, 106].

4.6. Nucleic Acids as Enzymes

Ribozymes are RNA molecules that act as catalysts: sequence-specific RNA endonucleases, nucleotidyl transferases, phosphatases, kinases, and glucanotransferases [37, 107]. The sequence-specific cleavage of oligodeoxyribonucleotides and single-stranded DNA can also be catalyzed by ribozymes [108]. Previously, only proteins (enzymes) were thought to have activities of this kind. Ribozymal properties were discovered in the early 1980s in the self-splicing introns of *Tetrahymena* [109] and ribonuclease P [110], which cleaves tRNA precursors and contains RNA as the catalytic subunit. In eucaryotes, small nuclear RNAs (snRNAs) are required for the splicing of pre-mRNA; they are part of the spliceosome, an RNA – protein complex [90].

The smallest RNA structure that exhibits catalytic (cleavage) activity is 19 nucleotides long and forms a hammer head structure with its target [111]. No pure DNA catalysts have been discovered yet [112]. However, since a few of the ribonucleotides in ribozymes can be replaced by deoxyribonucleotides, the three-dimensional structure that permits nucleic acid catalysis may not necessarily be limited to RNA [113, 114].

In all proven examples of RNA catalysis, the substrate attacked by the ribozyme is itself a nucleic acid. However, there are indications that rRNA also attacks other molecules (i.e., is an RNA enzyme). RNase P is the only known naturally occurring ribozyme that does not cleave itself, but attacks other molecules [72, 115].

5. Isolation, Purification, and Transfer

Chromosomal DNA from bacteria or eucaryotes has a very high molecular mass and is extremely fragile. Thus to isolate DNA, cells must be gently lysed with enzymes (pronase, protease K, lysozyme) and mild detergents. Accompanying RNA can be removed by treatment with enzymes which digest RNA or by gel filtration [116]. Proteins associated with DNA are denatured with phenol and extracted [117].

Plasmid DNA is relatively small and has a closed circular and supercoiled form. It is more stable than chromosomal DNA when subjected to shearing forces and can be renatured much more easily after denaturation; isolation and purification of plasmid DNA is achieved relatively easily (e.g., by equilibrium centrifugation in cesium chloride – ethidium bromide gradients at 150 000 – 400 000 g for 5 – 48 h). Kits are also available which permit the isolation of pure plasmid DNA in a short time without ultracentrifugation using binding to glass powder (glass milk) and/or gel filtration. Similar methods are used for the *isolation of RNA*. However, degradation by ribonucleases must be prevented (RNA is much more sensitive to nucleases than DNA). Either proteases or chloroform are employed to remove protein; with chloroform protein precipitates at the phase boundary. Phenol is not normally used because a small part of the RNA also goes into the phenol phase. Oligo(dT) cellulose (cellulose-bound oligonucleotides containing only thymine) can be used for the purification of eucaryotic mRNA [118] taking advantage of its poly(A) tails.

Nucleic acids can also be purified by ion-exchange chromatography (e.g., by HPLC) [119]. Suitable separating media are hydroxyapatite and anion exchangers. Reversed phase methods and gel filtration are also used.

Microgram amounts of DNA fragments can easily be isolated and purified by techniques such as electroelution from agarose gels, binding to anion-exchange paper, dialysis, or binding to glass milk (powdered glass suspension). After purification, DNA can easily be concentrated by precipitation with ethanol or 2-propanol.

DNA can be transferred relatively easily in vivo between related organisms (especially in bacteria) via endogenous mechanisms (e.g., conjugation, some viruses). Several other methods are available for the transfer of DNA in the laboratory: application as a $CaCl_2$ precipitate, exposure to an electric field (electroporation), and the use of viral vectors (see also → Genetic Engineering).

6. Analysis of Nucleic Acids

Sequencing. Computer data banks such as EMBL [120] and GenBank [121] contain sequence information in the order of millions of nucleotides.

Single or double-stranded DNA can be sequenced [122]. The most widely used methods are the Sanger method [123] and the Maxam and Gilbert method [124] (→ Genetic Engineering, Chap. 3.3.). In the Maxam and Gilbert method the DNA is cleaved with chemicals statistically and specifically at one of the four bases. The Sanger method employs enzymatic synthesis of a complementary copy of a single-stranded DNA template and random chain termination with dideoxynucleotides. Both methods produce DNA fragments that are separated by gel electrophoresis.

Both methods initially made use of radioactively labeled nucleotides and subsequent exposure on X-ray films for identification of the fragments. More recent variations use fluorophores [fluorescein, tetramethylrhodamine, Texas red, 4-chloro-7-nitrobenzo-2-oxa-1-diazole (NBD)]

which are more stable, easier to use, less dangerous, and permit the automatic detection of all four nucleotides on a single track. Sequences of > 450 bases can be determined per gel run and track [125–128]. An automatic sequencing machine allows determination of sequences of up to 10 000 bases per day. Further acceleration by combination with automatic DNA preparation in robotic workstations may be possible [129].

More recent techniques aim at faster sequence determinations (several hundred bases per second [130]) with smaller amounts of DNA. Variations of the Sanger method permit determination of sequences up to 10 000 bases without subcloning [131].

The Sanger method can also be used for sequencing RNA [132] and sequences up to 150 bases can be determined in a single run. Reverse transcriptase is used to synthesize DNA with RNA as a template. The RNA sequence is then deduced from the DNA sequence. Another method for RNA sequencing involves the use of specific RNases (→ Enzymes, Chap. 6.5.2.6.) [75, 76].

X-Ray Analysis. X-ray analysis is of considerable importance for elucidating the structure of nucleic acids and their building blocks [44]. Useable crystals can be obtained from aqueous solutions for molecules up to the size of tRNA (75 – 90 base pairs). Nucleic acids of higher molecular mass are too heterogeneous to produce crystals, quasi-crystalline fibers drawn from concentrated aqueous solutions are used instead.

Nuclear Magnetic Resonance (NMR). The best method for determining the structure of relatively short (10 – 20 bases or base pairs) DNA or RNA fragments in solution is ^{1}H-, ^{13}C-, ^{15}N-, or ^{31}P-NMR (one- or two-dimensional) [133, 134]. NMR is also used to study short triple helices [135], DNA – RNA hybrids in solution [136], DNA – drug complexes, mismatches, and intercalating agents. Torsion angles and the mobility of base pairs and the sugar phosphate backbone can be determined.

Electron Microscopy. Electron microscopy permits the determination of the length of DNA. DNA heteroduplexes, binding of large protein factors [137], and supercoiled DNA [138] can be visualized. A special application is DNA-hybridization electron microscopy [139, 140]: biotinylated DNA probes are hybridized to selected regions of DNA or RNA and then reacted with avidin and visualized by electron microscopy.

Scanning tunneling microscopy (STM) allows the observation of single-stranded DNA adsorbed on graphite with atomic resolution. It opens up the possibility of structural studies on DNA and of direct sequencing [141–143]. The profiles show excellent correlation with the results of X-ray analysis.

Centrifugation. Ultracentrifugation in cesium chloride gradients can be used to measure the molecular mass of DNA and also for the experimental identification of covalently closed circles. Sedimentation at alkaline pH (> 11.3) causes disruption of the hydrogen bonds and unwinding of the DNA molecules. In the case of linear DNA, two single strands are obtained which have a higher sedimentation coefficient than native DNA at salt concentrations > 0.3 mol/L. Covalently closed circles cannot be denatured into single strands, they collapse and have a sedimentation coefficient that is three times higher than that of native DNA.

In equilibrium centrifugation in cesium chloride, ethidium bromide is firmly bound to DNA in salt solutions by intercalating between base pairs. This lowers the density of the DNA by about 0.15 g/cm^3 and the DNA unwinds with increased binding of ethidium bromide. Unlike linear DNA, covalently closed molecules have a limited absorption capacity for ethidium bromide. Linear DNA is consequently lighter than covalently closed circular DNA. Use of a cesium chloride density gradient with ethidium bromide therefore permits the separation of supercoiled and linear (relaxed) DNA of the same size.

Staining and Quantification. Nucleic acids can be stained with ethidium bromide [144], Stainsall, 1-ethyl-2-[3-(1-ethylnaphtho[1,2 *d*] thiazoline-2-ylidene)-2-methyl-1-propenyl]-naphtho[1,2 *d*] thiazolium bromide [145], or silver [146–148]. DNA stained with ethidium bromide can be quantified in electrophoresis gels after being photographed [144, 149]. Silver staining followed by a densitometer scan is

equally sensitive (1 – 2 ng of DNA can be detected) [146]. A quick and sensitive estimation of the amount of nucleic acid can be obtained by measuring the UV absorption at 260 nm: an absorption of 1.00 corresponds to a concentration of ca. 50 µg/mL of double-stranded DNA.

DNA quantification in the picogram range has been reported with a silicon sensor, that responds to the interaction between DNA-binding proteins and DNA [150]. Quantification in the picogram range is also possible after specific hybridization (see Chap. 8).

Fluorescence imaging of DNA in picogram to nanogram amounts is made possible by laser excitation of a DNA – ethidium homodimer [5,5′-diazadecamethylene) bis(3,8-diamino-6-phenylphenanthridinium) dichloride dihydrochloride] complex at 488 nm [151].

Electrophoresis. Since DNA is negatively charged because of its phosphate groups, it migrates in an electrical field (usually at a pH of ca. 7). The electrophoretic mobility of DNA fragments in solution is independent of the molecular mass (constant linear charge density). However, electrophoresis of DNA in gel matrices (agarose or polyacrylamide) at a constant field strength is an effective method of separating DNA molecules according to molecular mass. The mechanism of separation is not well understood [152].

Important experimental parameters are gel concentration, field strength, temperature, and running time. Gels of 0.5 – 2 % are usually employed for the separation of 50 – 20 000 base pairs at field strengths of 2 – 3 V/cm [153]. The mobilities of linear and supercoiled DNA of equivalent molecular mass are different. Estimation of the molecular mass of supercoiled DNA molecules based on linear standards is therefore not possible.

Polyacrylamide gels (4 – 12 %) give a sharp separation of polynucleotides up to a length of about 600 base pairs. Special gels can separate polynucleotides with up to 2500 base pairs [148]. Mobility varies logarithmically with the size of the DNA at field strengths below 1 V/cm [154]. Separation efficiency is limited in the range of 10 000 – 50 000 base pairs, there is no resolution above 50 000 base pairs.

Denaturing gels (e.g., with urea) are used in the sequencing and analysis of single-stranded nucleic acids. Under special conditions, the behavior of individual DNA molecules in an electric field can be observed with a fluorescence microscope [155].

Pulse-field electrophoresis is used to separate larger linear DNA molecules. Here the direction of the electric field is changed at intervals. The DNA molecules therefore have to change their orientation, the time required for this change depends on the size of the DNA [44, 156]. Unlike conventional electrophoresis (duration 30 – 60 min), a pulse-field run takes 20 – 140 h. Usually, 1.5 % agarose gels are used and 10 – 20 µg of DNA can easily be separated at field strengths of 2.5 – 10 V/cm. Separation can be achieved up to ca. 12×10^6 base pairs [157]. Separation is affected by DNA topology and sequence, pulse time (seconds to minutes), field geometry, field strength, gel composition, sample concentration, temperature, and running time [154, 158].

7. Chemical Synthesis

The chemical synthesis of oligonucleotides began in 1955 when A. M. Michelson and A. R. Todd prepared the first dinucleoside monophosphate [159]. They used the so-called *triester method* to show that oligonucleotides of defined sequence can be prepared by purely chemical methods. In 1956 Khorana et al. successfully synthesized the same nucleotide by the *diester method* [160]. This process dominated oligonucleotide synthesis until the mid-1970s, and was also used by Khorana and coworkers for the first total synthesis of a gene (alanine-specific tRNA from yeast) [161]. The importance of synthetic oligonucleotides was generally underestimated because the synthesis was time-consuming and expensive. It was the progress in genetic engineering that resulted in a dramatic increase in the demand for synthetic oligonucleotides, which, in turn, led to the development of new synthesis concepts and to the automation of DNA and RNA synthesis.

7.1. Synthesis Strategy

The chemical synthesis of DNA consists of three steps:

1) Separate synthesis of the two complementary strands
2) Hybridization of the two strands (formation of hydrogen bonds between A and T, and between C and G)
3) Enzymatic joining of the DNA molecules to give larger DNA units

Three standard methods are used for the synthesis of the 3′,5′-internucleotide phosphodiester bond. They differ in the type of monomer building blocks used and are known as the phosphate triester, phosphoramidite (phosphite), and the *H*-phosphonate methods (Fig. 8, Section 7.4).

An oligomer can be synthesized either by stepwise addition of individual monomer building blocks or by joining oligomer blocks (e.g., dimers or trimers). The former concept is employed in solid-phase synthesis, which was developed almost simultaneously by R. B. Merrifield [162] for peptides and by R. L. Letsinger [163] for oligodeoxyribonucleotides. The first nucleoside (sugar and base) is covalently bound to an insoluble support at the 3′-OH group of the sugar. Stepwise synthesis of the chain then proceeds by condensation of the appropriate nucleoside monomers. Since the reaction product remains immobilized on the support, it can easily be freed of other reactants by washing; time-consuming chromatographic purification is not required. Synthesis is usually carried out on the 0.2 – 1 μmol scale and all

Figure 8. Chemical synthesis of oligodeoxynucleotides
DMT = 4,4′-dimethoxytrityl residue; MSNT = mesitylene sulfonylnitrotriazole; R = polymer support

reagents are applied in large excess. Solid-phase synthesis of oligonucleotides can be divided into the following steps:

1) Preparation of monomer units that are either protected or can be activated
2) Functionalization of the support
3) Stepwise synthesis of the desired nucleotide sequence by one of the three methods listed above
4) Cleavage of the protecting groups and the support
5) Isolation and purification of the desired sequence

7.2. Protecting Groups

In order to avoid unwanted side reactions during oligonucleotide synthesis, functional groups that do not participate in the linking reaction must be suitably protected. Only a few protective groups have gained acceptance and are based on the work of Khorana et al. [164].

Two types of groups can be distinguished: permanent and intermediary protecting groups.

Permanent protecting groups are maintained throughout the synthesis and protect the exocyclic amino functions of adenine, cytosine, and guanine; the OH group of phosphorus; and the 2′-OH group of ribose (in RNA synthesis). *Intermediary protecting groups* protect the 5′-OH group of the sugar and are cleaved after each condensation step.

The most important protecting groups are depicted in Figure 9. Adenine and cytosine are usually converted to the corresponding acid amides with excess benzoyl chloride, the amide of guanine is obtained with isobutyric anhydride. Base-protecting groups are introduced with a method developed by Ti et al. (transient protection) [165]. After termination of the synthesis, the protecting groups are removed with 32 % aqueous ammonia at 50 – 60 °C in 4 – 5 h. In long, guanine-rich sequences, the O-6 position of guanine can also be protected [166–169], usually with a 4-nitrophenylethyl residue [170]. This is especially important for attaining good yields in the triester process because otherwise sulfonation with the condensing agent easily occurs. More labile amidine or acyl base-protecting groups are of interest for the synthesis of phosphate-modified oligonucleotides because they are more sensitive to hydrolysis than their diester analogues and treatment with ammonia at 60 °C can cause considerable strand breakage [171–173]. Important examples of such groups are the 4-phenoxyacetyl residue

Figure 9. Protecting groups (bold type) used in the synthesis of oligonucleotides

(Pac) for adenine and guanine and the isobutyryl residue for cytosine.

The *tert*-butyldimethylsilyl residue is preferred as the protecting group for the sugar 2′-OH group in the solid-phase synthesis of oligoribonucleotides [174].

The 5′-OH group of deoxyribose or ribose is usually blocked with the 4,4′-dimethoxytrityl group [164], which can easily be removed after each coupling step by mild acid hydrolysis with 3 % di- or trichloroacetic acid in dichloromethane [175].

In the triester method the 2-chlorophenyl group is used to protect the phosphorus [176], while in the phosphoramidite method, the β-cyanoethyl group is preferred to the originally used methyl group [177, 178]. The β-cyanoethyl group can easily be removed at the end of the synthesis by β-elimination with aqueous ammonia [179]. No internucleotide phosphorus-protecting group is required in the *H*-phosphonate process.

7.3. Functionalization of the Support

Polystyrene [180], polyacrylamide [181], cellulose [182], and silica [183] have been used for solid-phase synthesis of oligodeoxyribonucleotides. The preferred support material is controlled pore glass (CPG) [184, 185] functionalized with a long-chain alkylamine spacer. The material is relatively rigid, does not swell, and is inert to all reagents used in the synthesis. In addition, it withstands the high mechanical stress encountered in the large number of reactions performed in automatic synthesizers. The narrow pore-size distribution gives more uniform diffusion parameters and, consequently, more reproducible flow rates and availability of functional support sites.

The support is functionalized with an alkylamine by silanization with 3-aminopropyltriethoxysilane [183, 186]. Heating and subsequent treatment with methanol result in cross-linkage of the silyl groups and hydrolysis of outer, less strongly fixed groups [187]. The nucleoside at the 3′-OH end of the DNA to be synthesized is linked to the support via a succinyl spacer [183, 188, 189]. Amino groups of the support that have not reacted are capped with acetic anhydride [188]. To determine the loading of the support with nucleoside material, an aliquot is treated with strong acid to remove the DMT residue. The resulting orange solution containing the dimethoxytrityl cation [190] can be determined by measuring the absorbance at 495 nm. The average loading is usually 15 – 25 µmol per gram of CPG.

7.4. Methods of Synthesis

The three main methods of oligonucleotide synthesis are the phosphate triester, the phosphoramidate (phosphite), and the *H*-phosphonate methods (see Fig. 8). The phosphoramidite method is the most widely used (Fig. 10, see next page). The reaction cycle involves

1) Cleavage of the 5′-OH DMT group
2) Condensation of the next monomer building block (chain elongation)
3) Masking of 5′-OH groups that have not reacted completely (capping)
4) In the phosphoramidite and *H*-phosphonate processes, an additional oxidation step is required after each condensation step or the end of the synthesis respectively to obtain the desired internucleotide phosphodiester.

Chain elongation in all processes occurs in the $3' \rightarrow 5'$ direction.

Phosphate Triester Method. This method was first used to synthesize oligonucleotides from suitable building blocks in solution [191–194]. It can also be employed for the solid-phase synthesis of nucleotides up to a chain length of about 20 bases. The monomer building block is a protected nucleoside phophodiester derivative (Fig. 8) [193] which reacts with the free 5′-end of a support-bound nucleoside to give a neutral phosphotriester. Various aromatic sulfonic acid derivatives [192, 195, 196], primarily mesitylene sulfonylnitrotriazole (MSNT), serve as condensing agents. The reaction can be accelerated by using catalysts such as *N*-methylimidazole [175]. This method is not widely used any longer due to disadvantages such as long reaction times, a large number of side reactions, and the frequently observed nicks caused by incomplete cleavage of the internucleotide protecting group.

Figure 10. Synthesis cycle according to the phosphoramidite method
B = base; DMTr = 4,4′-dimethoxytrityl residue

Phosphoramidite (Phosphite) Method. This concept is similar to the triester method, but chain synthesis involves trivalent phosphite triester intermediates. The preferred monomer building blocks are the so-called nucleoside phosphoramidites introduced by CARUTHERS et al. [177, 178] that can be activated with tetrazole. After each condensation step, the phosphite triester is converted to the phosphate triester by oxidation with iodine solution. The exceptionally high reactivity of the activated phosphoramidites results in a condensation time of ca. 1 min and $\geq 99\,\%$ yield per chain elongation step.

***H*-Phosphonate Method.** This synthesis method was developed almost simultaneously by GARREGG et al. [197] and by FROEHLER and MATTEUCCI [198]. Condensation is achieved by activation of nucleoside 3′-*H*-phosphonate monomers with pivaloyl or adamantoyl chloride. Since the *H*-phosphonate bond is not cleaved during the synthesis cycle, only one oxidation step is required at the end of the synthesis. This considerably reduces the duration of the cycle. Another advantage over the phosphoramidite method is the higher stability of the monomers. Moreover, excess *H*-phosphonates can be regenerated after the synthesis, thus reducing costs; this makes this method particularly interesting for large-scale synthesis. Since the dinucleoside *H*-phosphonate bond can be easily attacked by nucleophilic reagents [199], oligonucleotide thiophosphates or phosphoamidate analogues can easily be prepared by oxidation with sulfur or amines [199, 200].

Synthesis of Oligoribonucleotides. The solid-phase synthesis of oligoribonucleotides can be conducted by the phosphoramidite [174] or the *H*-phosphonate method [201]. An additional protecting group is required for the 2′-OH group of the ribose [195]. The *tert*-butyldimethylsilyl group has gained acceptance for solid-phase synthesis with ribonucleoside phosphoramidites. It is stable under the acidic conditions required to remove the DMT group and can

be cleaved with tetrabutylammonium fluoride at the end of the synthesis. However, steric hindrance due to the *tert*-butyldimethylsilyl group results in yields of ca. 95 % per chain elongation step. Hence, this method is suitable only for the synthesis of oligomers up to a chain length of about 40 nucleotides.

7.5. Cleavage of Protecting Groups and Purification of Oligonucleotides

Cleavage of Protecting Groups. After synthesis, the oligomer is still completely protected and attached to the support. Cleavage of protecting groups should always begin with the internucleotide protecting group on the phosphorus to prevent strand damage [196, 202].

If the triester method is used, the 2-chlorophenyl group is eliminated by treatment with an "aldoximate" [203]; the base-protecting groups and the support are subsequently removed with 32 % aqueous ammonia at 50 °C. Finally, treatment with 80 % acetic acid cleaves the DMT group, provided it is not required for purification by reversed phase high performance liquid chromatography (HPLC).

If methyl phosphoramidites are used for synthesis, the first deprotection step is treatment with thiophenol to cleave the methyl group [7]. If, however, β-cyanoethyl phosphoramidites are used, then ammonia treatment at 50 °C is sufficient to remove all protecting groups including the support.

Purification of Oligonucleotides. Since condensation does not give 100 % yields per coupling step, short-chain homologues are present in addition to the target sequence. For example, for an oligonucleotide with 70 bases and a 98.5 % yield per condensation step, the target sequence accounts for ≤ 35 % of the total yield. A purification step is therefore required for longer oligomers [204]. High performance liquid chromatography (HPLC) or polyacrylamide gel electrophoresis is commonly used for product isolation. Purification by *reversed phase HPLC* is ideal for the routine separation of oligonucleotides up to ca. 40 – 50 nucleotides [204, 205]. Here, the target sequence that is still tritylated is eluted last. Separation efficiency can be increased with special high-affinity protecting groups allowing purification of chains with 150 bases [206]. If the trityl group is removed before purification, the polyanionic character dominates. It is then more advantageous to separate the desired product by ion-exchange chromatography. *Polyacrylamide gel electrophoresis* under denaturing conditions is the most efficient method for oligonucleotide separation [207, 208]; the homologues are separated according to size. The target sequence, which is usually the longest sequence, has the lowest mobility. The individual fragments become visible on exposure to UV light (λ 254 nm) and are cut out of the gel matrix. Extraction with buffer or electroelution and subsequent desalting (dialysis or gel filtration) yield the desired oligonucleotide.

7.6. Synthesis of Modified Oligonucleotides

Oligonucleotides bind specifically to a defined target sequence under suitable hybridization conditions. Relatively short oligonucleotides ($<$ 20 bases) are used for new drug design strategies involving targeting interference of genetic expression at the level of transcription or translation [209].

For in vivo chemotherapeutic applications based on sequence-specific hybridization (antisense inhibition), nuclease-resistant oligonucleotides are required (the most important are shown in Fig. 11, see next page). They can be obtained by modifying the phosphate backbone of the oligonucleotides, by using α-anomers (**10**) or 2′-O-alkylribosides (**9**). In spite of the changes these oligonucleotides still hybridize with the target sequence and they can also pass through cell membranes more easily due to their lipophilic nature. Applications of these analogues as antisense oligonucleotides are summarized in [209–211].

Phosphothioate analogues (**1**), in which a nonbridging atom of the phosphate group is replaced by a sulfur atom either at a single specific position or at all positions within the chain, can be synthesized by following the phosphoramidite or *H*-phosphonate route [212–214]. The sulfurization reaction is usually carried out with a solution of sulfur in pyridine and carbon disulfide [215]. Other sulfurization reagents that

can also be used in the synthesis are described in [216, 217].

Figure 11. Modified oligonucleotides

Like native DNA, phosphorodithioate analogues (**6**) are stereochemically uniform products and can be prepared by the phosphoramidite method with the corresponding thiophosphoramidite monomers [218].

Methylphosphonates (**5**), phosphoramidates (**7**), and phosphotriesters (**8**) are nonionic and have a more hydrophobic character than naturally occurring nucleic acids. The synthesis of oligonucleoside methylphosphonates is described in [219–222], and is best carried out with nucleoside 3′-methylphosphonous acid imidazolide, which in turn is prepared from methylphosphonous acid bisimidazolide and the fully protected nucleoside. Alternatively, a *H*-phosphonate is reacted with *tert*-butyldimethylsilyl chloride to give silyl phosphite and subsequently oxidized with alkyl or aryl halides [223]. All of the early investigations on the biological activity of these oligonucleotide analogues (which were named "matagen", an acronym for mashing tape for gene expression) were conducted by Ts' O and MILLER [222].

Phosphoramidates (**7**) can be prepared by reacting *H*-phosphonate oligonucleotides with a solution of the appropriate amine in carbon tetrachloride [213].

The 2′-O-methylribonucleotides (**9**) are well established modified nucleosides that are used as monomer building blocks for oligonucleotide synthesis [224]. The synthesis of the corresponding nucleoside phosphoramidites is described in [225]. Oligonucleotides with α-2′-deoxynucleosides (α-DNA) form β-DNA with natural DNA. This form has parallel strands and is also nuclease resistant [226, 227].

To increase the binding of an oligonucleotide to the target, an intercalating agent (e.g., 2-methoxy-6-chloro-9-aminoacridine [228, 229] or phenazine [230]) can be covalently attached to the oligonucleotide. These agents insert "internally" between the base pairs of the double helix, increasing duplex stability.

A second method involves binding of photoreactive groups (e.g., psoralen [231–233], azidophenacyl or azidoproflavin derivatives, proflavins, and porphyrins [234–238]) that are activated by UV or visible light and can cross-link with the target DNA or RNA. "Sequence-specific artificial endonucleases" [239] are oligonucleotides that bear a group which can induce specific cleavage of the target nucleic acid after binding to the target. Such groups are the above-mentioned photoreactive groups: subsequent treatment with piperidine allows cleavage of the target sequence at the cross-linking site. Direct light-induced cleavage at neutral pH is achieved with ellipticine and diacapyrene derivatives [238]. Metal chelates attached to oligonucleotides (e.g., iron – EDTA [240–242], copper – phenanthroline [243–246], or iron – porphyrin [247]) lead to relatively specific cleavage of the target sequence. A nonspecific DNase or RNase bound to a complementary oligonucleotide can also destroy the target nucleic acid [248, 249].

Nonradioactive labeling of synthetic oligonucleotides has become an important technique in molecular biology and several chemical procedures have been developed. Oligonucleotides are covalently attached to "marker groups" such as fluorescent dyes, biotin, and other biologically active groups (see also Section 8.2). These reporter groups can be attached to an oligonucleotide at the 5′-OH terminus, the 3′-OH terminus, the phosphate backbone, or one of the bases. Attachment at the 5′-OH terminus via pro-

tected aminoalkyl or thioalkyl phosphoramidites is most common. These amino- or thiolinkers are added in the last synthesis step and produce a free amino or thiol terminal after cleavage of the protecting groups [250–252]. Subsequent reaction with the activated marker molecule (e.g., biotin-*N*-hydroxysuccinimide) gives the labeled oligonucleotide.

A large number of bifunctional linkers (e.g., maleimidohexanoyl-*N*-hydroxysuccinimide ester) have been described which allow coupling of enzymes [253], peptides, and proteins to linked oligonucleotides via amino groups of the amino acids or thiol groups of cysteine. Attachment at the 3′-OH terminus can be carried out by linking a ribose unit with T 4 RNA ligase, followed by periodate cleavage of the ribose ring, and subsequent reductive amination [254, 255]. Labeling via a 3′-terminal thiol group is described in [256]. Also a modified support is commercially available which produces an aliphatic primary amino group at the 3′-terminus [257]. At the internucleotide bond reporter groups can be attached, e.g., via a phosphoramidate linkage [258–260].

The attachment of reporter groups to modified bases usually occurs at the C-5 position of pyrimidines or the C-8 position of purines [261]. During oligonucleotide synthesis, a fully protected deoxyuridine phosphoramidite [262] modified with a trifluoroacetylaminopropenyl residue is inserted at the desired position in the sequence (usually at C-5); after cleavage of the protecting groups, the group to be coupled is bound via the resulting amino function. Numerous other labeling positions have been described (e.g., the C-4 position [263–265] of 2′-deoxycytidine and the N-6 position of the adenine ring [266] or the exocyclic amino function of the guanine residue [267]).

8. Uses

The direct use of nucleic acids in *nucleic acid probe technology* is becoming increasingly important. Here, labeled nucleic acids are used as probes to detect other nucleic acids by means of hybridization [21, 23]. Identification of the specific nucleotide sequence of a pathogen (virus, bacterium, parasite) can be used to diagnose an infection [268, 269]. More complex analyses are often necessary for the detection of changes in nucleic acids (point mutations, deletions, insertions, translocations, expression level or number of copies of the genetic information) in the diagnosis of hereditary diseases [24], or in the investigation of tumors [25, 26]. This chapter will be limited to describing the uses of nucleic acids in probe technology but other applications will first be briefly summarized.

The second important field of application for nucleic acids is *genetic engineering* (→ Genetic Engineering) which allows the production of proteins in bacteria, fungi, animal or plant cell cultures, or in animals or plants. The nucleic acid that codes for the desired protein is introduced into the organism and expressed.

Antisense technology

is a third field of application of nucleic acids which, however, still only exists in model systems. This technology aims to prevent the expression of nucleic acid sequences that have a negative effect on an organism. This can be achieved by the interception and binding of mRNA with synthetic antisense oligonucleotides (see Section 7.6) or with an antisense RNA from a recombinant expression system. The mRNA forms double strands with the antisense RNA by specific base pairing and cannot be translated [270, 271]. Another method of stopping expression is the specific cleavage of the target nucleic acid by catalytic RNA (ribozymes) [270, 271]. The target nucleic acid is recognized by specific base pairing with the ribozyme. Antisense technology may be used to treat infections caused by viruses, bacteria, or parasites by cleaving or preventing the expression of the genetic information of these pathogens. Another possibility is the treatment of diseases resulting from overexpression of an endogenous gene or its expression in an erroneous target cell.

Finally, nucleic acid technology offers great promise in *research*. As a result of the dramatic improvements in cloning and sequencing large sections of DNA, DNA sequences or genes are increasingly being used as a starting point for the analysis of a biochemical mechanism. Nucleic acid sequences are also used to study evolutionary relationships between different organisms by comparing sequences of conserved genes.

8.1. Hybridization Techniques for Nucleic Acid Detection

Nucleic acid hybridization is based on the fact that two complementary nucleic acid strands (DNA – DNA, RNA – RNA, DNA – RNA) associate to form a double strand according to the rules of base pairing (see also → Genetic Engineering, Chap. 3.1.). The nucleic acid to be detected must be present as a single strand, i.e., denaturation of double strands is required before hybridization. The nucleic acid probe must contain a sequence complementary to that of the nucleic acid under investigation and have a label to permitidentification of the double strands formed by hybridization.

Solid-Phase Hybridization. The labeled hybrid strands must also be distinguishable from unhybridized probes. The simplest way of doing this is to use methods in which the nucleic acid of interest is bound to a solid phase (usually a nitrocellulose or nylon membrane). The potential nonspecific binding sites for the probe on the solid phase are blocked prior to the hybridization reaction with unlabeled nucleic acids of different origins, proteins, and polymers. Consequently, the labeled probe only binds to the solid phase via specific base pairing to the target nucleic acid. The unbound probe is subsequently washed away.

In the *dot blot process* nucleic acid samples are spotted on a membrane [272]. After hybridization the detection of bound label reveals which spots contain the nucleic acid of interest. Quantification is possible by comparison with the signal from a standard [273].

In *Southern blotting* (→ Genetic Engineering) the DNA to be analyzed is separated according to size by gel electrophoresis and subsequently transferred to a membrane without changing the spatial distribution of the DNA fragments [21, 274]. After hybridization the size of the fragment containing the sequences of interest can be analyzed. Analogous separation and hybridization of RNA is referred to as *Northern blotting*.

In *in situ hybridization* the nucleic acid of interest is fixed in such a manner that its natural cellular compartmentalization is maintained [21, 23, 275]. As in histological studies, entire cells are applied and fixed to microscope slides or tissue is cut into ultrathin layers and fixed. Hybridization takes place on the slide between the labeled probes and the nucleic acids in the sample material. Examination under the microscope reveals which and how many cells contain the nucleic acid of interest, as well as its subcellular location. In situ hybridization permits differentiation between individual cells, whereas in solid-phase blotting methods the nucleic acids from many cells are mixed together. In situ hybridization also permits the assignment of a nucleic acid sequence to a chromosome by analyzing cells that are in the metaphase of cell division [276, 277]. The areas of the chromosomes containing the complementary sequences are specifically labeled by the nucleic acid probe.

Hybridization in Solution. Hybridization reactions in which both reaction partners are in solution are more efficient. The hybridized probe, as part of a double strand, can be separated from the unreacted single-stranded probe by *electrophoresis* or *chromatography*.

Figure 12. Sandwich hybridization
The oligonucleotide detection and capture probes are labeled with two different labels.

Sandwich hybridization offers an alternative way of separating hybrids formed in solution (Fig. 12) [278, 279]. The nucleic acid of interest is hybridized with two different probes that recognize different sections of the nucleic acid. One of the probes (detection probe) is labeled to allow detection of the hybrid. The second probe acts as a capture probe to bind the hybrid consisting of the nucleic acid of interest and the detection probe to a solid phase. The detection probe only binds to the solid phase if the

nucleic acid of interest is present in the solution and forms a bridge between the two probes. The capture probe can be covalently coupled to the solid phase [280], or can be labeled with a molecule that is distinct from the detection label and is bound to the solid phase via a fixed antagonist. Examples are biotin-labeled probes with a streptavidin- or avidin-loaded solid phase [281] or antigen-loaded probes with an appropriate antibody on the solid phase.

Strand displacement is another method for detecting hybrids formed in solution (Fig. 13) [282, 283]. Here, the probe is a hybrid of a short, labeled oligonucleotide and a longer nucleic acid strand forming a partially single-stranded, partially double-stranded molecule. The longer strand is complementary to the nucleic acid of interest. If the nucleic acid of interest is present in the assay, double strands are formed with the single-stranded region of the probe. This double-stranded region of the unlabeled probe strand and the nucleic acid of interest is longer than the double-stranded region formed between the two probe strands. Therefore complete hybridization occurs between the longer probe strand and the nucleic acid of interest. As a result the short, labeled probe strand is released and can be detected.

Figure 13. Strand displacement
ss = single-stranded; ds = double stranded

Finally, there are a series of modifications of a hybridization principle which does not require the separation of bound from unbound probe. Here, two labeled probes hybridize with the nucleic acid of interest at adjacent positions. Spatial proximity of the two labels is only guaranteed if the nucleic acid of interest is present and produces a signal that can be measured (e.g., enzymatic activity, light of a certain wavelength) [284].

8.2. Labeling and Detection Systems

Radioactive labeling is losing importance due to the development of sensitive, nonradioactive labels. Nucleic acids are usually radioactively labeled by enzymatic incorporation of nucleotides containing ^{3}H, ^{35}S, or ^{32}P isotopes with polymerases. Alternatively, the 5′-OH terminus of DNA can be labeled with ^{32}P by polynucleotide kinase [21]. Radioactive nucleic acids are detected by exposure to X-ray film or a photoemulsion (in situ hybridization) or by measurement in a scintillation counter.

In nonradioactive methods, the nucleic acid can be directly labeled with a fluorescent or luminescent dye [285], bound to an enzyme (e.g., β-galactosidase, horseradish peroxidase, alkaline phosphatase) or coupled with biotin or a hapten (antigenic determinant) [284]. The hapten (or biotin) is detected by the binding of an appropriate antibody (or streptavidin/avidin). The antibody and streptavidin/avidin are, in turn, directly coupled to a dye molecule or to an enzyme [21]. Additional chemical methods for labeling nucleic acids are described in [21, 286–288] and in Section 7.6.

Photolabeling is a simple and fast labeling method [21, 289]. Biotin or a hapten is coupled to a photoreactive group (photobiotin [289], photodinitrophenyl phosphate (DNP) [290], or photodigoxigenin [291]) which reacts with the amino groups of the nucleotides. On irradiation with light the photoreactive group is activated resulting in the formation of a covalent bond between biotin or the hapten (DNP, digoxigenin) and the nucleic acid.

Nucleic acids from biological sources (e.g., plasmids) are usually labeled with the aid of enzymes. Modified nucleotides are inserted with polymerases [21]; DNA polymerases are used to insert the deoxyribonucleotide triphosphate derivatives (e.g., biotin – dUTP, biotin-dATP, digoxigenin – dUTP, bromo – dUTP, and fluorescein – dUTP) in nick

translation (→ Enzymes, Chap. 6.2.1.) or by random primed labeling. The 3′-terminus of nucleic acids can be labeled with these nucleotides by terminal transferase (→ Enzymes, Chap. 6.2.5.). Modified ribonucleotides (e.g., biotin – UTP and digoxigenin – UTP) are inserted into RNA probes by in vitro transcription with RNA polymerases, particularly with phage-coded RNA polymerases [21, 22] (→ Enzymes, Chap. 6.3.).

Figure 14. Polymerase chain reaction (PCR)

8.3. Amplification Systems

The sensitivity limit of nucleic acid probe technology can be increased by specifically amplifying (i.e., increasing the amount of) the nucleic acid of interest [21].

Polymerase Chain Reaction (PCR). The polymerase chain reaction is an established technique [15, 27, 292, 293] which is used to amplify a particular nucleic acid from a complex mixture of sequences. The amplified DNA can be subsequently sequenced and/or cloned using genetic engineering techniques, or can be used to increase the sensitivity of pathogen detection. The sensitivity can be increased to such an extent that, for instance, one genome from the human immunodeficiency virus (HIV) integrated in the DNA of a single cell can be detected in the presence of many uninfected cells.

The PCR is based on the repetition of three partial reactions in 20 – 50 cycles (Fig. 14):

1) An oligonucleotide primer is annealed to each of the two denatured complementary strands of the DNA sequence to be amplified.
2) Primer extension catalyzed by a DNA polymerase converts the region to be amplified into two double strands.
3) The double strands are denatured by heating.

Theoretically the number of templates can be doubled in each cycle, so that 2^n templates would be created in n cycles; 25 cycles would result in an amplification rate of 3.4×10^7. However, the partial reactions are not perfectly efficient, and amplification rates of ca. $(1-3) \times 10^6$ are obtained in 25 cycles. Implementation of the PCR is facilitated by the use of thermostable DNA polymerases because otherwise new polymerase would have to be added at the start of each cycle. Typical PCR cycles consist of a few minutes of primer annealing at ca. 55 °C, a few minutes of elongation at ca. 70 °C, and 1 – 2 min of denaturation at 95 °C. These steps can be carried out automatically in programmable "thermocyclers".

RNA can also be amplified by PCR if a DNA template is created in the first step with the help of reverse transcriptase. The PCR product can be detected by electrophoresis with or without previous cleavage with restriction endonucleases, and with or without hybridization with a probe. The PCR product can be labeled directly by using labeled primers [294] or by incorporating labeled nucleotides (Section 8.2) [295, 296]. Con-

tamination is a serious problem in PCR because of the enormous sensitivity of the method. For example, contamination of a sample with a single molecule of the DNA of interest can lead to an incorrect positive result.

Other Amplification Systems. In *transcription-based amplification* oligonucleotide primers are annealed to the nucleic acid of interest which, in addition to complementary sequences to the target, also contain a promoter (binding site) for RNA polymerase [297]. After primer elongation RNA polymerases are used to produce RNA transcripts starting from the promoters. The transcripts can be converted to DNA with reverse transcriptase and used again as targets for the oligonucleotide primers.

The *ligase chain reaction* uses a ligase instead of a polymerase in temperature cycles analogous to the PCR [298, 299]. Two oligonucleotides are annealed adjacent to one another on the template strand and joined by a ligase. The ligated strand is then removed by denaturation and two oligonucleotides can anneal again in the next cycle.

Other amplification systems do not require cycles with different temperatures but proceed isothermally. In *self-sustained sequence replication* (3 SR) [300] and *nucleic acid sequence based amplification* (NASBA) [301], three enzymes act simultaneously at a constant temperature to amplify the target sequence. Reverse transcriptase synthesizes DNA on an RNA template by extending oligonucleotide primers that contain promoter sequences for RNA polymerases. The RNA strand of the resulting DNA–RNA hybrid is digested with RNase H allowing double-stranded DNA to be produced by reverse transcriptase with a second primer. RNA polymerase then transcribes the double-stranded DNA starting at the promoters, and the resulting RNA is again converted to DNA with reverse transcriptase.

Another isothermal amplification technique is based on the replication of RNA genomes with the help of *Qβ replicase*–a RNA-dependent RNA polymerase from phage Qβ [302, 58]. Natural substrates of Qβ replicase are characterized by RNA sequences forming a special secondary structure. For nucleic acid detection these sequences are modified by the insertion of short probe sequences. Unlike the amplification methods described above, the target sequence itself is not multiplied, instead the probe is amplified after it has located the target sequence (signal amplification). Nonspecifically bound and contaminating probe molecules cause background problems that can be alleviated by repeating the hybridization in cycles (reversible target capture) [303].

Another method of signal amplification involves the formation of probe networks in which the target-specific probe has target sequences for secondary probes. A "Christmas tree" of labeled probe sequences is produced for each original target molecule [304–306].

8.4. Applications of Probe Technology

Detection of Infectious Microorganisms. Detection of nucleic acids can be used to identify pathogenic viruses, bacteria, or parasites. In comparison with the detection of proteins or antigens, nucleic acid detection has the advantage that it allows identification of infectious organisms that frequently change their antigens (e.g., HIV) or that exist in a variety of serotypes. Furthermore, viral infections can be detected at the latent stage when no detectable synthesis of viral proteins occurs (e.g., HIV or herpes viruses). DNA probe technology can be more sensitive than immunological techniques due to the possibility of nucleic acid amplification. Although immunological tests are still easier, faster, and cheaper, competitive nucleic acid tests are to be expected in the future.

Detection of the nucleic acid of a pathogen can also serve as a direct measure of the infectiousness of a patient or test material [307]. Quantitative determination of the pathogenic nucleic acid can be used to follow the progress of treatment.

Detection of viruses is possible with a broad spectrum of nucleic acid probes, ranging from synthetic oligonucleotides to the complete cloned viral genome. Infections caused by some virus groups (e.g., papilloma viruses or enteroviruses [308]) can be diagnosed with a probe containing group-specific sequences identical in all members of the group and by using probes with nucleic acid sequences specific for each member.

For the detection of bacteria, the fact that each bacterium contains approximately 10 000 ribosomes and thus 10 000 copies of rRNAs can be used to increase the sensitivity level. The rRNA sequences are relatively well conserved and can used to establish relationships between different organisms in phylogenetic trees. Tests for individual bacterial species, for groups, or even for a wide range of bacteria can be carried out with appropriate oligonucleotide probes [309]. Another group of nucleic acid probes contains sequences of bacterial pathogenicity factors and allows differentiation between pathogenic and apathogenic types of a species (e.g., *Escherichia coli*) [268, 269]. Analogously, detection of resistance genes permits detection of antibiotic resistance and simultaneous identification of the pathogen [310]. Bacterial identification is also applied in the detection of pathogens in food (e.g., *Salmonella*).

Detection of Human DNA Sequences. Nucleic acid probe technology can be used for the *diagnosis of hereditary diseases* and *genetic counseling* [24]. If the genetic basis of the disease is known, the alteration in the nucleic acid can be detected by hybridization with the appropriate region. Such alterations include point mutations (sickle-cell anemia), deletions (Duchenne's muscular dystrophy), or variations in expression (forms of thalassemia). If the genetic cause of the disease is unknown, genetic markers that are inherited together with the defect gene are analyzed, e.g., recognition sites for restriction enzymes (restriction fragment length polymorphism, RFLP) [311].

The analysis of human sequences can also be applied in *tumor diagnosis* [25, 26]. Some human tumors are associated with characteristic chromosomal changes or alterations in genes (oncogenes) [312]. Suitable nucleic acid probes can be used for the highly sensitive detection of DNA sequences of different chromosomes connected by chromosomal translocations or for the detection of mutations in oncogenes that are associated with tumors. For instance, the Philadelphia chromosome (a translocation between chromosome 9 and 22) is characteristic for chronic myelogenous leukemia [313]. Point mutations in the *ras* oncogene are associated with several tumors, and amplification of the *N-myc* gene with neuroblastomas. In the case of recessive oncogenes (tumor suppressor genes) [314, 315], the loss of gene expression results in a tumor; for example, the loss of the retinoblastoma gene results in an eye tumor, retinoblastoma. Another area of tumor diagnosis is the detection of clonality of a leucocyte population caused by the transformation of a white blood cell [316]. Since all lymphocytes have their own characteristic rearrangement of immunoglobulin genes or T-cell receptor genes, the appearance of a defined pattern in many lymphocytes indicates proliferation of a single cell.

Methods that use the genetic diversity of humans to study individuals have wide applicability. Determination of the genes of the major histocompatibility locus (HLA) can be used both for diagnosis (transplantation medicine, prediction of risk of disease, autoimmune diseases) and for differentiation between individuals [317]. Probes which hybridize with repetitive sequences that occur in each individual in a slightly different, genetically determined arrangement can be used for finger printing [28]. Here nucleic acids cleaved by restriction enzymes are separated electrophoretically and hybridized with these probes in the Southern blot technique (Section 8.1). Several fragments of different sizes, each containing these repetitive sequences, produce a signal. Each individual inherits half the sequences from the father and half from the mother, and therefore has a unique fragment pattern [318–320]. This technique is used in forensic medicine to identify criminals by DNA isolated from cells (hair, blood etc.). Other fields of application are in the determination of paternity and family relationships.

9. Nucleosides and Nucleotides

9.1. Nucleosides

The term nucleosides was originally applied to the ribose derivatives of purines that can be isolated from an alkaline RNA hydrolysate. Later, this name was given to all purine and pyrimidine *N*-glycosides of D-ribose and 2-deoxy-D-ribose. Today, this term refers to all natural or synthetic compounds which consist of a heterocyclic nitrogen-containing base (aglycon) and a carbohydrate residue (glycon). The nitrogen atom (*N*-nucleoside) or carbon atom (*C*-

nucleoside) of the heterocycle is linked to the anomeric carbon atom of the sugar residue.

Ribonucleosides and deoxyribonucleosides are obtained from naturally occurring RNA and DNA by enzymatic or chemical hydrolysis. Most nucleosides are stable within a wide pH range. However, under strongly acidic or alkaline conditions at elevated temperature cleavage of the *N*-glycosidic bond may occur. The purine nucleosides are adenosine [*58-61-7*], deoxyadenosine [*958-09-8*], guanosine [*118-00-3*], and deoxyguanosine [*961-07-9*]. The pyrimidine nucleosides are cytidine [*65-46-3*], deoxycytidine [*951-77-9*], thymidine [*50-89-5*], and uridine [*58-96-8*].

Figure 15. Common nucleosides

The furanoses D-ribose and 2-deoxy-D-ribose are linked to the bases by a β-glycosidic bond at C-1 (Fig. 15). A limited number of nucleosides in the α-D configuration (e.g., 5,6-dimethylbenzimidazole-α-D-ribofuranoside of vitamin B 12) can be isolated from natural substances.

Rare nucleosides and nucleoside antibiotics are found in biopolymers as fermentation products of microorganisms or as building blocks of nucleic acids [29] (see also → Antibiotics, Chap. 3.4.). They exhibit structural modifications of the nucleobase or the glycon residue.

An example of a rare building block of viral DNA is 2′-deoxy-5-hydroxymethylcytidine (**11**) and those of tRNA are the hypermodified nucleosides queuosine [*57072-36-3*] (**12**) and wyosine [*52662-10-9*] (**13**).

Examples of nucleosides formed by microorganisms are tubercidin [*69-33-0*] (**14**), formycin [*6742-12-7*] (**15**), cordycepin [*73-03-0*] (**16**), blasticidin S [*2079-00-7*] (**17**), vidarabin [*24356-66-9*] (**18**), oxetanocin [*103913-16-2*] (**19**), aristeromycin [*19186-33-5*] (**20**), neplanocin A [*72877-50-0*] (**21**), sinefungin [*58944-73-3*] (**22**), and tunicamycin A [*66081-37-6*] (**23**, $n = 9$), tunicamycin B [*66081-36-5*] (**23**, $n = 10$), tunicamycin C [*66081-37-6*] (**23**, $n = 8$), and tunicamycin D [*66081-38-7*] (**23**, $n = 11$) (Fig. 16).

Naturally occurring nucleosides show a wide variety of biological effects. Accordingly a large number of derivatives have been synthesized in order to find useful chemotherapeutics [30]. The 2′,3′-dideoxyribonucleosides are important synthetic nucleoside derivatives with modified sugar moieties. In the cell the 5′-triphosphate derivatives of these compounds inhibit the reverse transcriptase of retroviruses and thus are potentially important therapeutic drugs (e.g., 3′-azidothymidine [*30516-87-1*] (**24**) (AZT), the first approved drug against HIV infection, see → HIV and AIDS Therapy, Chap. 2.2.).

Figure 16. Nucleosides formed by microorganisms

Other derivatives which contain only a part of the ribofuranosyl residue (e.g., acyclonucleosides) also show antiviral activity. This class of substances includes acyclovir (**25**), ganciclovir (**26**) and phosphonylmethyl analogues [e.g., (*S*)-9-(3-hydroxy-2-phosphonylmethoxypropyl) adenine (**27**)]. Nucleosides with a halogen substituent in the heterocyclic moiety are important antiviral drugs (e.g., 5-iodo-2′-deoxyuridine, 5-bromovinyl-2′-deoxyuridine (**28**), or 2-chloro-2′-deoxyadenosine).

The nucleosides are obtained by modification of existing nucleosides or total synthesis. Total synthesis can be carried out in a linear or convergent manner. Due to the chiral centers on the glycon residue, preparation of optically pure nucleosides requires stereoselective methods of synthesis, especially for the glycosidation of the aglycons. The most important methods of total synthesis will be described briefly. Detailed surveys of the chemical synthesis of and on nucleoside derivatives are given in [31–35].

Synthesis of *N*-Nucleosides. The first syntheses date back to the work of Fischer and Helferich who condensed acetyl-protected α-D-glucopyranosyl halides with the silver salts of heterocycles. The analogous chemical synthesis of the natural nucleosides adenosine and guanosine was described by Todd and coworkers [321]. This method was improved after the introduction of the chloromercury purine derivatives [322] and the use of mercury cyanide (which avoids the tedious preparation of the heavy metal salts of the nucleobases) [323]. The Hilbert–Johnson method was developed for the preparation of pyrimidine nucleosides [324]. This method starts with 2,4-dialkoxypyrimidines, which yield the corresponding nucleosides on reaction with O-acetyl-protected

1-halogenosugars (glycosyl halides) and subsequent ammonolysis or hydrolysis of the 4-alkoxy intermediates [325].

The introduction of the melt process according to SATO [326] represented another advance in nucleoside synthesis. Here, a polyacylated sugar is heated with the purine or pyrimidine base and a catalyst (e.g., 4-toluenesulfonic acid or zinc chloride) in vacuum. This method has the advantage that the free heterocyclic bases (instead of their heavy metal salts) and the 1-O-acetyl sugars (instead of the corresponding glycosyl halides) can be used.

Another synthesis, developed simultaneously by BIRKHOFER and coworkers [327] and NISHIMURA and coworkers [328], involves reaction of trialkylsilylated heterocycles with peracylated 1-halogenosugars in the presence of silver perchlorate as catalyst.

This method was improved by VORBRÜGGEN and is a silyl version of the Hilbert–Johnson method [329]. It is the method of choice for the synthesis of pyrimidine nucleosides. A similar process is based on transglycosylation, i.e., the transfer of the sugar residue of a nucleoside (donor) to a heterocyclic base (acceptor). Apart from chemical transglycosidation, enzymatic sugar transfer is also possible [330].

An elegant method for the synthesis of the nucleosides of purines or purine analogues, developed by SEELA and coworkers, is based on phase transfer catalysis [331]. It gives high yields of the desired β-anomers and the anomeric ratio can be controlled by the choice of catalyst. Finally, reference should be made to the synthesis of the heterocyclic moiety from the C-1 functionalized sugar molecule [332]. This is the method of choice for the synthesis of carbocyclic nucleosides [333].

Synthesis of *C*-Nucleosides. Two methods are available for synthesizing the C–C linkage between the glycosidic and the aglyconic parts of the molecule [334]:

1) Synthesis according to the Fischer–Helferich principle
2) Synthesis via a preformed function on C-1 of the sugar

Unlike *N*-glycosides, the glycosidic bond of *C*-nucleosides is stable to acids and these compounds are not attacked by nucleoside phosphorylases. Consequently *C*-nucleosides are more stable than *N*-nucleosides in biological systems.

9.2. Nucleotides

The term nucleotide generally refers to the phosphate esters of nucleosides. Only mononucleotides (i.e., nucleotides consisting of only one nucleotide unit) are considered here. Mononucleotides can be joined together to form an oligonucleotide (up to 200 nucleotide units) or a polynucleotide (> 200 nucleotide units).

Nucleotides are obtained by the chemical or enzymatic hydrolysis of nucleic acids and by the chemical or enzymatic phosphorylation of nucleosides [335–339]. They may be ribonucleotides (from RNA) or 2′-deoxyribonucleotides (from DNA). Depending on the position at which the sugar moiety is phosphorylated nucleotides can exist as 2′-, 3′-, or 5′-phosphoric acid monoesters. Cyclic 2′,3′- and 3′,5′-phosphoric acid diesters can be formed by intramolecular dehydration.

Cyclic adenosine monophosphate [*60-92-4*] (cAMP) is especially important as a mediator of the action of a large number of hormones (second messenger) [340].

Adenosine
3′,5′-monophosphoric acid
(cyclic AMP)

Cyclic AMP is formed in the cell from ATP by the enzyme adenylate cyclase. It was first synthesized in the laboratory by COOK and coworkers [341]. Numerous attempts have been made to specifically alter the pharmacological effects of cAMP by chemical modification [342].

The nucleotides can contain more than one phosphate group. The 5′-triphosphates of the ribonucleosides and 2′-deoxyribonucleosides of the purines adenine (ATP or dATP) and guanine

(GTP or dGTP) and of the pyrimidines cytosine (CTP or dCTP) and thymine (dTTP) or uracil (UTP) are the most common natural nucleotides. They serve as building blocks for the polymerase-catalyzed synthesis of nucleic acids. Adenosine 5′-triphosphate [*56-65-5*] is also the main source of chemical energy in the living world.

Adenosine
5′-triphosphoric acid
(ATP)

In contrast to many nucleosides, the corresponding phosphate esters are readily soluble in water as their alkali salts. Although the nucleoside monophosphates are stable compounds, the corresponding nucleoside di- and triphosphates undergo slow hydrolytic cleavage of the pyrophosphate bond, even at ambient temperature and neutral pH. Nucleoside mono- and polyphosphates are dephosphorylated by phosphatases (phosphomonoesterases) to yield the corresponding nucleosides.

Analogues containing modified phosphate groups (e.g., thiophosphate [343], imidophosphate [344], or methylene phosphonate functions [345]) are not or only very slowly attacked by phosphomonoesterases. The triphosphate derivatives of those analogues which are only slightly modified compared to the parent nucleotides are valuable tools for studying the reaction mechanisms of ATP-dependent enzyme systems.

The naturally occurring cyclic nucleoside 3′,5′-monophosphates are also very stable. They are converted to acyclic 5′-monophosphates by specific phosphodiesterases. Other important nucleotide building blocks occurring in nature are the adenosine phosphate residues in nicotin-amide adenine dinucleotide phosphate [*53-59-8*] (NADP), coenzyme A [*85-61-0*], and flavine adenine dinucleotide (FAD) [*146-14-5*].

β-Nicotinamide adenine dinucleotide phosphate
(NADP)

Coenzyme A

Synthesis of Nucleotides. For a review of chemical nucleotide syntheses, see [346]. Nucleoside monophosphates are usually prepared by chemical phosphorylation of the nucleosides with phosphorus oxytrichloride. If the reaction is carried out with a trialkyl phosphate as solvent the 5′-monophosphates are obtained almost exclusively [347]. Protection of the 2′- and/or 3′-OH functions of the sugar is not required. Various methods are available for the chemical synthesis of nucleoside di- and triphosphates from nucleoside monophosphates.

In the *morpholidate method* the nucleoside monophosphate is reacted with morpholine and dicyclohexylcarbodiimide to give the corresponding phosphomorpholidate [348]. The latter is subsequently reacted with orthophosphate to give the nucleoside diphosphate or with pyrophosphate to yield the nucleoside triphosphate.

In the *imidazolidate method* the nucleoside monophosphates are reacted with 1,1′-carbonyldiimidazole to give the corresponding nucleoside monophosphate imidazolidates [349]. These compounds are in turn treated with inorganic ortho- or pyrophosphate to yield the nucleoside di- or triphosphates. In comparison with

the morpholidate method, this process has the advantage of being a "one-pot" reaction.

In the *anhydride method* the nucleoside monophosphates are reacted with diphenyl chlorophosphate [350]. The resulting nucleoside diphenyl pyrophosphates can be subjected to nucleophilic exchange by treatment with anions such as ortho- or pyrophosphate.

These methods can be used analogously to prepare the nucleotides of the coenzyme type by replacing the orthophosphate with, for example, sugar phosphates. The possibility of reacting the nucleoside phosphodichloridate, obtained after treatment with phosphorus oxytrichloride, directly with pyrophosphate in a "one-pot" reaction has been described [351].

Enzymatic syntheses of nucleotides are described in [335–338].

9.3. Therapeutically Important Nucleoside and Nucleotide Derivatives

Antiviral Derivatives. The strategies involved in the development of antiviral nucleosides are reviewed in [352]. For the development and applications of antiviral active nucleotide analogues, see [353]. Of the large number of compounds that have been synthesized since the early 1970s, only a few derivatives have so far been approved. Among them are:

1) 5-iodo-2′-deoxyuridine [*54-42-2*] (IDU)
2) 5-trifluoromethyl-2′-deoxyuridine [*70-00-8*] (trifluorothymidine, TFT)
3) 9-β-D-arabinofuranosyladenine [*24356-66-9*] (Ara-A, vidarabin) (**18**)
4) 3′-azido-3′-deoxythymidine [*30516-87-1*] (AZT, zidovudine) (**24**)
5) 1-β-D-ribofuranosyl-1,2,4-triazole-3-carboxamide [*36791-04-5*] (ribavirin, virazol)
6) 9-[(2-hydroxyethoxy)methyl]guanine [*59277-89-3*] (acyclovir) (**25**)

The following nucleoside analogues are active against HIV infections. However, clinical trials of these compounds are still incomplete or they have not yet been approved partly because of serious side effects:

1) 2′,3′-dideoxycytidine [*7481-89-2*] (ddC), 2′,3′-dideoxyadenosine [*4097-22-7*] (ddA), and 2′,3′-dideoxyinosine [*69655-05-6*] (ddI)
2) 9-(1,3-dihydroxy-2-propoxymethyl)guanine [*82410-32-0*] (ganciclovir, DHPG) (**26**)
3) (*E*)-5-(2-bromovinyl)-2′-deoxyuridine [*73110-56-2*] (BVDU) (**28**)

For further details, see → Chemotherapeutics, Chap. 4.6.1. → Chemotherapeutics, Chap. 4.6.8.

Antitumor Derivatives. For details, see → Cancer Chemotherapy, Chap. 2.4.

1. Introduction

Historically, the quality of motor gasoline and the technical development of the spark ignition Otto engine were closely connected. Since its invention in 1876, the Otto engine technology has been continuously improved, a process which is still going on.

Of particular importance for this development was the parallel improvement in gasoline knock resistance. Knock resistance is one of the most important gasoline properties and its improvement allowed the engine manufacturers to increase the compression ratio. This in turn resulted in higher engine efficiency and improved exhaust emission performance. The knock resistance is measured in terms of gasoline octane numbers in accordance with worldwide standardized test procedures.

Figure 1 (see next page) shows, for Germany as an example, the close relationship between octane number and engine compression ratio from the turn of the century until now. Over this period a variety of measures were applied to improve refinery technologies to meet the increasing engine octane demand. These measures incorporated the integration of complex processing plants, from which a range of gasoline component streams with different octane levels became available. In 1929, *alkyllead compounds* were introduced in the United States as efficient octane enhancers. Thereafter these were used generally to improve the gasoline octane quality until environmental concerns led to their use being stepwise restricted worldwide. The resulting shortfall of octane was compensated by improvements in refinery processes, as well as by the use of alternative octane enhancers such as fuel oxygenates. Starting in the 1970s a number of *fuel oxygenates* became available and were increasingly used for gasoline blending.

More recently, efforts to reduce air pollution led to the enforcement of more restrictive exhaust emission limits for vehicles. In this context, passenger cars with catalytic converters were introduced. Since the addition of lead to gasoline results in the deactivation of the cat-

alytic converters, unleaded gasoline of high octane quality was consequently made available.

Figure 1. Trend of research octane number and compression ratio in Germany

2. Technical Information

2.1. Combustion in Otto Engines

(→ Automotive Fuels, Chap. 2.1.)

During the compression stroke the air – fuel mixture is compressed to 1.5 – 2.5 MPa and the temperature rises up to 1000 K, depending on the engine compression ratio. The mixture composition and the engine condition are controlled in such a way that the upper flammability limit of the mixture is not exceeded i.e., no self-ignition occurs. Shortly before the piston reaches the upper dead point, combustion is initiated by an electrical discharge between the electrodes of the spark plug. The appropriate spark timing is essential for engine efficiency. Best efficiency is achieved when maximum chemical energy released from the combusted charge is transformed into mechanical energy during the expansion stroke. The spark transports the necessary ignition energy to form a self-sustained flame kernel in the air – fuel mixture. Subsequently this flame kernel expands and flame fronts propagate spherically into the combustion chamber. The speed of flame propagation depends on a variety of parameters.

First of all the process is affected by the initial status of the air – fuel mixture with respect to temperature, pressure, and turbulence. Since the combustion process is exothermic, temperature and pressure increase rapidly. This accelerates the flame propagation, which in turn affects the status and turbulence of the burned gas as well as the unburned charge ahead of the flame. The entire combustion consists of a complex interaction of fluid dynamics, reaction kinetics, radical diffusion, and radiation processes.

2.2. Knock Phenomena

Average flame speeds in the engine combustion process range from 10 to 30 m/s. In contrast, flame speeds of 300 to 500 m/s are measured under knocking conditions. The knock phenomena typically occur at the end of the normal combustion process (Fig. 2). They originate from zones of unreacted charge where the critical conditions in terms of temperature and pressure are exceeded. This causes spontaneous self-ignition which in turn results in a sharp pressure increase.

Figure 2. Pressure profile versus crank angle during combustion
A) Normal combustion; B) Knocking combustion

The detailed processes occur very rapidly and involve the complex coupling of fluid dynamic and reaction kinetic processes. Despite a large number of experimental and theoretical studies the phenomenon itself is not fully understood [1].

The phenomenological process, however, is readily detectable. It is characterized by a typical high-frequency noise emitted from engine parts. Knocking combustion results in high mechanical stress and thermal overload of the engine. Finally, it leads to severe damage to pistons, piston rings, seals, and/or cylinder heads.

2.3. Octane Number Measurement

The knock resistance of gasolines is measured by their research octane number (RON) and motor octane number (MON). Both are determined

in single cylinder engines according to standardized test procedures. The design of the engines, their mode of operation, and the calibration and measuring methods are complex; detailed descriptions are given in ASTM D 2699 (RON) and ASTM D 2700 (MON) and in equivalent ISO and EN standards (→ Automotive Fuels, Chap. 3.1.1.). Measurement of MON is performed under higher engine severity than the RON measurement in terms of intake air, temperature, and engine speed. The MON describes high speed and high load knock behavior in productional engines whereas the RON is a measure for knock performance under acceleration conditions.

3. History

Until the mid-1920s there was only one gasoline grade available in most countries, predominantly produced from straight-run crude oil products which were selected according to their composition of aliphatic and aromatic components. In order to meet the increasing octane demand, e.g., indicated by the introduction of a premium grade in 1924, several refinery processes were developed. Today, a typical refinery produces up to twenty individual product streams used for gasoline blending (→ Automotive Fuels, Chap. 4.1.). The octane enhancement of tetraethyllead (TEL) was discovered in 1922 in the United States by T. Midgley, Jr. [2]. It was produced by the Ethyl Gasoline Corporation and first introduced onto the U.S. market in 1929. In Germany it became available shortly before World War II as an octane enhancer. TEL and TML (tetramethyllead) are so-called "lead fluids" and are still used in some parts of the world. However, leadalkyl compounds have disappeared from gasoline in most countries due to environmental concerns and because lead deactivates catalytic converters.

Other octane enhancers–except fuel oxygenates–never achieved any significant degree of application. The current dominance of unleaded gasolines in the market, however, causes octane shortfalls. This situation has led to renewed attention to additional octane sources, including both new and known oxygenates and alternative octane enhancers. Therefore, octane enhancers may play a more pronounced role in the future provided that environmental aspects are satisfied, such as toxicological properties and full compatibility with modern exhaust emission control systems.

4. Types of Octane Enhancers

Octane enhancers are substances which result in octane improvements when added to gasolines. This definition also includes all hydrocarbon-based refinery streams of sufficient octane quality. These streams, however, must be regarded as conventional gasoline blendstocks and are not covered in this article, in spite of the fact that some are traded as octane enhancers e.g., aromatic refinery fractions such as toluene.

Alternative ways to improve octane quality involve the use of special chemical compounds. Since these compounds have to be readily soluble in gasolines they must be hydrocarbon-based. They may, however, contain functional groups with heteroatoms such as oxygen, nitrogen, sulfur, phosphorus, halogens, or metal atoms. Depending on the compound concentration in the fuel, components and additives can be distinguished. *Components* are compounds blended in quantities which also affect gasoline properties other than octane number, such as heating value, density, or vapor pressure. In contrast, *additives* are applied in the ppm-concentration range so that other fuel properties are essentially unaffected. This discrimination reflects the fact that additives are much more efficient than components. Additives consist exclusively of organometallic compounds. When combusted they form solid oxidation products (ash) in addition to gaseous combustion products.

5. Ashless Octane Enhancers

Components are always added in higher quantities, and must, therefore, consist of "ashless" compounds. Only oxygen- or nitrogen-containing functional groups are suitable for octane enhancement. Sulfur-, phosphorus-, or halogen-containing compounds either promote knocking or achieve only insignificant octane improvements.

5.1. Blend Octane Numbers

When a component is blended to a base gasoline, the resulting octane number of the mixture cannot be calculated from the octane numbers of the neat gasoline and the component. Furthermore, the octane number of the mixture is not proportional to the component concentration. In order to characterize the octane efficiency of a component, therefore, "blend octane numbers" (B-ON) are defined according to the following equation:

$$\mathrm{B-ON} = \frac{\mathrm{ON_M} - \mathrm{ON_{BG}}\,(1-x)}{x}$$

where B-ON is the blend octane number of the component; $\mathrm{ON_M}$ the octane number of the mixture; $\mathrm{ON_{BG}}$ the octane number of the base gasoline; and x is the volume fraction of the component in the blend. All parameters on the right-handside of this equation must be determined experimentally. This equation attributes the entire change in octane number to the component. Graphically (Fig. 3), it reflects a linear extrapolation from the base gasoline $\mathrm{ON_{BG}}$, via the mixture $\mathrm{ON_M}$, to a fictive B-ON value of the neat component. If the calculated B-ON is compared with the measured octane number of the neat component ($\mathrm{ON_C}$), two alternatives are possible. If the B-ON is larger than the measured $\mathrm{ON_C}$, the mixture has a "synergistic" property, if the B-ON is smaller than the $\mathrm{ON_C}$, the mixture shows an "antagonistic" behavior.

Figure 3. Graphic interpretation of blend formula

An example of the nonlinear MON blend behavior and the determination of the B-MON value is shown in Figure 4 for straight-run gasoline – MTBE mixtures. This example shows that the extrapolated B-MON value based on $x = 0.2$ is higher than the experimentally determined MON value of neat MTBE, indicating a synergistic effect of MTBE.

Figure 4. Example of MON blend behavior of straight-run gasoline – MTBE mixtures

In general, B-ON values of octane enhancers and refinery components depend on the component concentration, as well as the octane level and the composition of the base gasoline. These dependencies on the base gasoline are relatively small for refinery components. For some octane enhancers, however, in particular oxygenates such as alcohols, the B-ON values vary significantly with gasoline composition. Therefore, in refinery blending, different B-ON data are used for the same oxygenate when blended to different gasoline grades. Normally, B-ON data derived from paraffinic gasolines are higher than those from gasolines with high olefinic and/or aromatic contents. Most components achieve higher B-RON than B-MON values. Both depend on the component concentration as can be seen in Figure 4 for B-MON. In practice, this effect can be neglected because the concentration range used is normally small.

Some other properties such as density, volatility, and vapor pressure also exhibit non-

linear blend behavior in mixtures. Blend properties are determined analogously to B-ON and play an important role in the evaluation of the economic potential of a component.

5.2. Nitrogen-Containing Components

The influence of nitrogen-containing compounds on octane performance has been studied extensively [3]. Depending on the functional group and the molecular structure, they provide either proknock (i.e., they promote knocking) or antiknock properties.

Whereas *organic nitrates* and *aliphatic amines* were generally found to promote knocking, *aromatic amines* achieve relatively high octane enhancements. Examples of B-ON values determined for aniline and some aniline derivatives are shown in Table 1. All measurements were performed in the same base gasoline with a component addition of 2 vol %. The octane enhancement efficiency varies with molecular structure. Relative to aniline, differences are small when hydrogen atoms of the aromatic ring are substituted by methyl or ethyl groups. Substitution with longer aliphatic chains results in reduced efficiency. Whereas primary and secondary amines have good octane enhancing properties, tertiary amines e.g., *N*,*N*-dimethylaniline are ineffective.

Table 1. Blend-octane numbers of nitrogen-containing components (values determined from 2 wt % addition to premium base gasoline)

Component	B-RON	B-MON
3,4-Dimethylaniline	370	320
3,5-Dimethylaniline	340	310
p-Toluidine	340	305
p-Ethylaniline	320	300
Diphenylamine	310	300
Aniline	310	290
p-tert-Butylaniline	300	260
N-Methylaniline	280	250
Indoline	300	150
N,*N*-Dimethylaniline	95	84

A serious *disadvantage* of nitrogen-containing components results from the fact that nitrogen is partially oxidized in the combustion process. This increases nitrogen oxide emissions in the exhaust gases. There is also experimental evidence that some of the components may cause deposit formations in fuel intake manifolds and/or combustion chambers, when used at the required concentrations. Of the listed components, only *N*-methylaniline was used as an octane enhancer for a short period after World War II in Germany.

5.3. Oxygen-Containing Components

Organic oxygen compounds such as alcohols, ketones, ethers, esters, and phenols are commonly characterized as "oxygenates" or "fuel oxygenates". The majority of the oxygenates act as octane enhancers; their efficiency depends, however, on the functional group and on the individual structure of the molecule. Some derivatives of esters, ketones, and phenols achieve relatively high B-ON values, as indicated in Table 2. Because of other inappropriate properties e.g., high boiling points, high acidity, low material compatibility, and high toxicity they are not used as octane enhancers.

Table 2. Blend octane numbers of selected oxygenates

Component	B-RON	B-MON
3,4-Dimethylphenol	180	180
Phenol	190	160
m-Cresol	160	150
o-Cresol	160	140
Dimethyl succinate	130	130
Acetylacetone	120	110
Acetone	107	98

Of the oxygenates, only alcohols and ethers are used to any significant extent. They are preferred over other octane enhancers because of lower costs, availability, handling, and their physical and chemical properties, which are similar to gasoline components. Names, abbreviations, formulae, and molecular mass of the most important alcohols and ethers suitable for fuel blending are listed in Table 3.

5.3.1. EC Directive on Fuel Oxygenates

The use of oxygenates in gasolines was established during the 1970s and has developed rapidly to a large-scale business. Prior to any official regulation, the German automobile and oil industry reached an interindustrial agreement to restrict the methanol content of fuel to 3 vol% with the obligation to use an adequate cosolvent component (e.g., TBA) to ensure appropiate water tolerance of methanol-containing fuels. For

Table 3. Important fuel oxygenates

the EC the European Council passed a directive in December 1985, regulating the use of oxygenates in gasolines after several years of intensive negotiations of the ministries of commerce supported by experts [4]. Meanwhile, the technical annex of the directive has been implemented in the gasoline standards of all EC member states.

The purpose of the directive was to ensure:

1) The performance of the existing car population
2) The use of gasoline extender and octane-enhancing components in addition to materials derived from crude oil
3) The compensation of octane shortfall due to lowering of alkyllead concentration
4) A harmonization of gasoline quality in Europe

Table 4. EC directive on fuel oxygenates

Oxygenate	A, ∗ vol%	B, ∗∗ vol%
Methanol (stabilizers to be added)	3	3
Ethanol (stabilizers may be added)	5	5
Isopropanol (IPA)	5	10
tert-Butanol (TBA)	7	7
Isobutanol (IBA)	7	10
Ethers, with five or more C atoms	10	15
Other oxygenates, defined	7	10
Total oxygen content, wt %	2.5	3.7

∗ A = limits which have to be accepted by all EC countries.
∗∗ B = limits which may be adopted by individual member states but above which labeling is mandatory.

The annex lays down definitions and blend compositions of oxygenates. The most important information is summarized in Table 4, providing the maximum volumetric additions of individual oxygenates and the maximum gravimetric oxygen content of the blends.

5.3.2. Blend Octane Numbers of Oxygenates

The octane efficiency of oxygenates cannot be characterized in a simple way because it depends on a variety of factors. Therefore, B-ON ranges are usually defined to account for their possible variation. This makes it difficult to compare octane efficiencies of different oxygenates.

To overcome this problem, Veba Oil conducted a series of investigations with the objective to characterize the octane blend behavior of some oxygenates. In the progress of this work, the gasoline sensitivity (SEN, i.e., the difference between RON and MON) was found to be a suitable correlation parameter [5]. Empirically it may be considered as an approximate gauge for the gasoline composition; a high paraffinic content corresponds to low SEN, high aromatic and/or olefinic contents result in high SEN.

The measurements were performed in a variety of different unleaded gasolines, the compositions of which were widely varied. Oxygenate concentrations ranged from 10 to 20 vol%. Examples of the graphic correlations based on linear regression of B-ON data versus gasoline

Figure 5. Correlation between B-ON and SEN for methanol

Figure 6. Correlation between B-ON and SEN for PTBE

SEN are shown in Figure 5 for methanol and in Figure 6 for PTBE. Both B-RON and B-MON decrease with increasing gasoline SEN. Similar blend behavior was found for the majority of the oxygenates investigated. Typically, lower alcohols such as methanol and ethanol show a strong dependence of B-ON on SEN. For higher alcohols and ethers this dependence is less pronounced; in a few cases, e.g., for TBA, no significant dependence was observed.

5.3.3. Other Properties of Oxygenates

Beside their octane efficiency, there are other properties of oxygenates which also affect the gasoline quality. Again their blend behavior may not be linear so that blend properties must be determined analoguously to the B-ON procedure. Selected properties of alcohols and ethers used as oxygenates are listed in Table 5.

Table 5. Properties of oxygenates

Oxygenate	*mp*, °C	*bp*, °C	d_4^{20}	n^{20}	Heat of combustion, kJ/mol	RVP ∗	Composition, wt %

∗ RVP Reid vapor pressure ASTM D 323.

Density. Densities of alcohols are generally higher than the specified density region for gasolines, whereas those of ethers range within it. Blend densities of alcohols and ethers show only moderate differences when compared to the densities of the neat components.

Vapor Pressure. Due to their polarity, lower alcohols such as methanol and ethanol possess blend vapor pressures (B-VP) which exceed the vapor pressure of the neat components, because association of alcohol molecules is hindered in the mixture. Therefore, their B-VP values strongly depend on the component concentration. In contrast, B-VP data of ether components hardly show any dependence on concentration. They are significantly lower than those of lower alcohols and are similar to the vapor pressure of the neat components.

Volatility. The addition of oxygenates affects the boiling characteristics of the gasolines. When ethers are blended, only moderate changes in the distillation curves are observed. Blends of lower alcohols, however, cause significant deformations of the distillation curves due to the formation of azeotropes. This rises the front-end volatility, i.e., an increased distillate fraction in the temperature range of the alcohol boiling points is obtained.

5.3.4. Production

The important processing data of alcohols and ethers are summarized in [6]. Further details of production and economics are described in [7].

Alcohols.

Methanol is produced catalytically from synthesis gas (→ Methanol, Chap. 4.). Apart from its use as a gasoline blending component, large amounts of methanol are also employed as feedstock for the etherification with isobutene to form MTBE (→ Methyl Tert-Butyl Ether, Chap. 3.).

Synthetic ethanol is produced by the hydration of ethylene with an acid catalyst such as sulfuric acid and phosphoric acid in reactor columns or in ion-exchanger fixed-bed reactors (→ Ethanol, Chap. 4.1.→ Ethanol, Chap. 4.2.). *Bioethanol* (→ Ethanol, Chap. 5.) is produced by fermentation of monosaccharides such as glucose, fructose, mannose, or xylose derived from molasses, sugarcane, sugar, corn, or potatoes. Costs of bioethanol are higher than those of synthetic alcohol because the process economics depend essentially on the feedstock price.

Higher alcohols i.e., 2-propanol, 1-butanol, 2-butanol, and 2-methyl-2-propanol can also be produced by hydration with acid ion-exchanger resins [8]. *Tert*-butanol (TBA) is formed as a coproduct in the production of propylene oxide by epoxidation of propene with *tert*-butyl hydroperoxide (TBHP) (→ Propylene Oxide). In the case of high MTBE demand in the market, TBA is sometimes dehydrated to isobutene which is then fed to the MTBE process [9].

Ethers. The ethers are chiefly manufactured by exothermic reaction of branched olefins bearing the double bond at the branching point with alcohols such as methanol, ethanol, 2-propanol, or butanol according to:

[for MTBE $m = n = p = 1$; for PTBE $m = n = 1$, $p = 3$; for *tert*-amyl methyl ether (TAME) $m = 2$, $n = p = 1$].

MTBE is the most important ether used as an oxygenate. MTBE capacity (see Fig. 7) and plant construction have increased steadily because MTBE blending offers simple and economic flexibility to fill any octane gap in the refiner's gasoline pool [10]. More than 40 % of the total onstream capacity of MTBE is used as merchant MTBE, which is available to supply refiners in need of additional octane quality [11]. For production of MTBE, see → Methyl Tert-Butyl Ether, Chap. 4.

Figure 7. Worldwide MTBE capacity trends (1989 survey)

Reaction of ethanol with isobutene produces ethyl *tert*-butyl ether (ETBE), which has similar properties to MTBE. This process offers an outlet of bioethanol [12, 13]. Reaction of 2-propanol with isobutene yields *PTBE* [14, 15], an oxygenate with excellent blend properties such as low vapor pressure and low oxygen content in combination with high octane quality.

Based on a similar technology methylbutenes (amylenes) of C_4 to C_6 streams can be etherified with methanol to *TAME* [16, 17], a blending ether with a high octane number. The BP Etherol process [18] uses unsaturated C_5 compounds of cracker fractions. Branched olefins react with methanol to form higher ethers. However, most of the branched olefins have terminal double bonds with low reactivity. To increase the yield of 3-methyl-2-butene (isoamylene) the double bond is shifted in the presence of a palladiumimpregnated cation-exchanger resin. The isomerization proceeds according to:

Isoamylene can then be reacted with methanol to form TAME.

5.3.5. Environmental Protection

The compulsory use of oxygenates in gasolines is becoming widespread in the *United States*, because several investigations have shown that oxygenates reduce carbon monoxide emissions. This effect offers a means of bringing CO emissions down to required standards. Depending on the area and season in the United States, the minimum oxygen content in the fuel is in the range of 2.0 – 3.0 wt % oxygen (Clean Air Act Amendment) [19]. Addition of TBA and methanol may reduce the CO emissions up to 40 % and the hydrocarbon emissions up to 20 % in comparison with conventional gasoline [20]. Insufficient supply of oxygen in air – fuel mixtures causes incomplete combustion of the fuel, accompanied by CO formation. When oxygen is supplied by oxygenates that are blended to the gasoline, this chemically available oxygen reduces the formation of carbon monoxide. Governments of several states made efforts to establish the relationship between fuel oxygen content and CO exhaust concentrations. In 1988, the state of Colorado mandated a minimum of 1.5 wt % oxygen in gasoline from January to March; this program was continued from November 1988 until March 1989, this time a minimum of 2.0 wt % oxygen was required. The 1988 program was estimated to lower CO air concentrations by 8 – 10 % along the Front range of the Rocky Mountains [10]. In the United States emission measurements with different vehicles show CO reduction up to 32 %, during the Federal Test Procedure (FTP) cycle (a standardized driving cycle for emission tests) [21]. The tests included vehicles with different exhaust and closed-loop systems and demonstrated a statistically significant CO reduction due to the oxygenated fuels, depending on the system and oxygen content (Fig. 8). The gasolines were blended with MTBE and ethanol. Emissions of unburned hydrocarbons and nitrogen oxides were virtually unaffected.

Figure 8. CO emissions FTP 75

Under *European conditions*, studies were made with ethers and alcohols on the influence of oxygen content on the limited pollutants such as carbon monoxide, hydrocarbons, and nitrogen oxide [5]. Blend components were methanol with IPA – TBA as cosolvents and the ethers MTBE, PTBE, and BTBE. Another investigation was conducted by the European Fuel Oxygenates Association (EFOA) using mixtures of ethers and alcohols to study the dependence on oxygenates systematically [22]. Oxygen content was varied up to 3.6 wt %. The results showed that oxygenates reduce CO emissions to a large

degree. The reduction increases with oxygen content but is not a function of the type of oxygenate.

5.3.6. Toxicology and Occupational Health

MTBE. Similar investigations of toxicity and other potential health effects of MTBE were performed. Animal testing to date has indicated that after ingestion, inhalation, or even injection of MTBE, it is mostly excreted unchanged [4].

PTBE. The Ames test does not show any mutagenity. According to an acute toxicity study in rats, PTBE is considered to be nontoxic up to a dose of 2000 mg per kilogram body weight.

5.3.7. Storage and Transportation

The higher ethers MTBE, PTBE, and TAME are stable in the presence of air under atmospheric conditions. Formation of peroxides is not observed during contact with oxygen. Containers, sealing materials, and also elastomers in automobiles have to meet the same requirements as for contact with gasoline.

6. Metal-Containing Additives

A large number of organometallic compounds are known to act as octane enhancers. Generally, compounds containing Pb, Cu, Ni, Th, Fe, and Mn achieve high octane improvements, whereas those containing Co, Zn, Bi, V, Se, and Ce are slightly less effective. For practical use, most of them must be excluded because of high costs, instability, toxicity, impact on catalytic converters, or other undesired properties.

Their use in gasolines also requires an official approval in most European countries and in the United States. In Germany, the application of metal-containing additives–other than lead–is restricted by the gasoline lead act (Benzin – Blei – Gesetz).

The octane enhancement of organometallic additives is explained by a catalytic effect, because during combustion the metal compound is oxidized to form very fine solid particles of metal oxide. These particles have large surface areas with active centers which can react with free radicals formed by partial oxidation of the gasoline. Therefore the spontaneous combustion is delayed and knocking does not occur. The consumed centers are reactivated by oxygen and can react again with free radicals. Due to this cycle only small concentrations of additive are necessary to cause high octane enhancement.

A metal-free component is unable to delay the spontaneous combustion catalytically. The organic compounds are consumed irreversibly by the intermediate reactants which are responsible for knocking. Therefore the effectivity of antiknocking components is limited and high concentrations are needed to get a higher octane quality.

A disadvantage of metal-containing additives results from the formation of solid combustion products that lead to deposit accumulation in the combustion chambers. For the lead fluids this problem was solved by addition of lead scavengers. However, this is unfeasible for most other organometallic additives, thus their use must be restricted to very low concentrations. Additives that achieve sufficient octane improvements in the ppm concentration range and that meet other technical and economical requirements are methylcyclopentadienylmanganese tricarbonyl (MMT) and dicyclopentadienyliron (ferrocene).

6.1. Alkyllead Compounds

The strong octane-boosting effect of tetraethyllead (TEL) was discovered in 1921 in the United States [23]. Its wide use began in the United States in 1929 and in Germany shortly before World War II. Curiously, investigations at that time regarded lead as relatively environmentally friendly.

The effect of lead is based on an intervention in the mechanism of the combustion process. In precombustion reactions, organic peroxides are formed, which decompose to form free radicals. The latter initiate knocking reactions. These highly reactive radicals can be deactivated by very finely divided lead compounds formed from the alkyllead compounds in the combustion chamber [24, 25].

In addition to tetraethyllead, which was used exclusively at first, tetramethyllead (TML)

came into use from 1960 onward. Mixed alkyllead compounds, such as diethyldimethyllead or ethyltrimethyllead, and mixtures of TEL and TML were also employed, because a broad-spectrum effect can be achieved through a combination of different characteristics (Table 6). Thus, the comparatively low boiling point of TML is good for increasing the front octane number. (Fig. 9).

Table 6. Comparison of TEL and TML

Chemical and physical properties	Tetraethyllead	Tetramethyllead
	$(C_2H_5)_4Pb$	$(CH_3)_4Pb$
Molecular mass, g/mol	323.5	267.3
Lead content, %	323.5	267.3
Density, g/cm^3	1.66	1.995
bp, °C	200 (decomp.)	110
Vapor pressure (20 °C), Pa	34	31.5×10^2

Figure 9. Effect of tetraethyllead and tetramethyllead on the gasoline front octane number (FON)

The increase in octane number that can be achieved with alkyllead compounds depends strongly on fuel composition. The *lead susceptibility,* a measure of the response behavior to the addition of lead, decreases in the following order: paraffins >> cycloparaffins > aromatics > olefins > diolefins (≈ 0). Accordingly, fuel components rich in paraffins, such as straight-run gasoline, alkylate, and isomerate (see → Automotive Fuels, Chap. 4.), react very well to lead addition, whereas olefin-rich catalytically cracked gasoline has a poor response (Fig. 10).

Figure 10. Effect of tetraethyllead on some base fuels (octane quality of the base fuel types are widely varying in practice)a) Olefin-rich fuel; b) Aromatic-rich fuel; c) Paraffin-rich fuel

In connection with the addition of alkyllead compounds to gasoline, the term "lead bonus" was sometimes used. It meant that highly leaded fuels, in comparison with unleaded or low-lead ones, have a disproportionately high road octane number, although the RON and MON determined in test engines are equally high [26–30]. Investigations carried out with the introduction of unleaded fuels showed, however, that low-lead and unleaded fuels behave almost identically with regard to the road octane number [31] in most cases.

Usually, alkyllead compounds have always been used in combination with scavengers. These are organochlorine and -bromine compounds, namely, 1,2-dichloroethane and 1,2-dibromoethane. In the combustion chamber, scavengers cause the formation of lead chloride and lead bromide whose good volatility at high temperature ensures that ca. 70 – 80 % of the lead is not deposited there. However, investigations in 1989 have shown that scavengers can be removed without adverse affects when the lead concentration in the fuel is low (e.g., 0.15 g/L).

On the other hand, treatment of leaded fuels with an antioxidant is necessary. Tetraethyllead, in particular, is prone to oxidation over long storage periods, leading to the separation of solid residues that can lead to blockages in the fuel system.

Originally, the addition of lead to gasoline was considered to be safe to the environment. This opinion has steadily changed, however [32–34], so that a decrease in the maximum permitted lead content has been legislated virtually worldwide. In the United States, Japan, Canada, Australia, Europe, and other areas leaded fuels have practically disappeared from the market. From a toxicological point of view, however, not only the lead but also the scavengers connected with it are suspected to be health risks, because these can form traces of highly toxic halogenated dibenzodioxins and -furans in the combustion chamber [35]. However, not only the poor compatibility of leaded fuels with the environment but also their incompatibility with catalytic converter technology (catalyst poisoning, see → Automobile Exhaust Control) has driven the move to unleaded gasoline in many parts of the world.

Alkyllead compounds protected also unhardened valve seats, present in older engines. Here, lead compounds formed in the combustion chamber inhibited erosion and wear ("recession") of the valve seats in two ways: (1) by avoiding high-temperature corrosion and (2) by their effect as solid lubricants. However, nontoxic alkali-metal additives are now available for this purpose, e.g., Powershield (Lubrizo) Formula Shell (Shell) Valve Master (Du Pont). Practically the only suppliers of alkyllead compounds are Ethyl and Octel.

6.2. Methylcyclopentadienylmanganese tricarbonyl

Methylcyclopentadienylmanganese tricarbonyl (MMT) [*12108-13-3*], is an organometallic additive used as an octane enhancer at low concentration. MMT is a metallocene compound in which the delocalized electrons of the cyclopentadienyl group are partially donated to the manganese atom and form covalent bonds. Carbon monoxide has a lone electron pair on the carbon atom which is donated to the manganese atom to form the carbonyl bond. In Canada it has been blended to unleaded gasoline for many years at a concentration of 0.0165 g Mn per liter of gasoline. In the United States, MMT is used in combination with alkylleads in leaded gasoline. Ethyl Corporation (Orangeburg) is the U.S. producer of MMT.

History. Ethyl Corporation discovered MMT in 1954 and introduced it into the U.S. market as a supplement to TEL in 1958. Evaluation in unleaded gasoline was made in 1969. From 1974 to 1979 MMT was used in unleaded gasoline.

The effect of MMT was tested on a series of in-use three-way catalysts. Catalyst activity was measured and compared to the activity of the catalyst without MMT operation. Steady-state and light-off temperature measurements indicated a reduction in catalyst efficiency as exposure to MMT was increased [37].

The EPA predicted that over the useful life of vehicles, a greater number of MMT-fueled vehicles would not meet their designed hydrocarbon emission standard compared with corresponding vehicles fueled without MMT. Based on these results and in accordance with Clean Air Act Amendments, the EPA banned MMT in 1979 for unleaded gasoline [38].

In 1983 production of MMT was ca. 1800 t/a.

Trade names: AK-33 X, Antiknock – 33, Combustion improver – 2.

Physical Properties [39]. MMT is sparingly soluble in water (70 ppm at 25 °C) and soluble in hydrocarbon solvents. MMT is a dark orange (straw color) liquid with a herbaceous odor; *mp* − 2.2 °C, *bp* 232.8 °C.

Chemical Properties. When heated to decomposition MMT emits toxic fumes of CO.

Production. The methylcyclopentadiene dimer [*26472-00-4*] is added to molten sodium suspended in diethylene glycol dimethyl ether at 185 to 190 °C. At this temperature, the dimer splits into the monomer and reacts with sodium to form sodium methylcyclopentadienide:

Anhydrous, flaked manganese chloride is added to the reaction mixture. The reaction forms bis(methylcyclopentadienyl)manganese with sodium chloride as byproduct. In the next step carbonylation under a pressure of 4.3 to 4.5 MPa at 190 °C forms MMT. Pure MMT is subsequently separated by fractional distillation.

Octane Enhancement. MMT can enhance between 0.5 and 1.0 (RON + MON)/2 per 0.01 g Mn/L, depending on gasoline composition, octane level, and leaded or unleaded basestock.

Toxicology and Occupational Health. MMT is a poison by ingestion, inhalation, skin contact, intravenous, and intraperitoneal routes (Table 7). MMT is included in the EPA's Extremely Harzardous Substances List. Manganese and some compounds are on the Community Right To Know List.

6.3. Ferrocene

In the early 1930s iron pentacarbonyl was used commercially as an octane-enhancing additive in Europe in concentrations similar to those of lead at that time. During combustion in engines iron pentacarbonyl formed excessive amounts of iron oxides which caused engine wear and influenced spark plug operation.

Ferrocene is another iron compound with similar octane-enhancing properties. Ferrocene [*102-54-5*] or dicyclopentadienyliron, $Fe(C_5H_5)_2$, belongs to the metallocenes; the iron atom is centered between two parallel cyclopentadiene rings. Ferrocene was first synthesized by MILLER, TEBOTH and TREMAINE in 1952. The sandwich or doublecone structure was first elucidated by G. WILKINSON and E. O. FISCHER.

Physical Properties. Important physical data of ferrocene are listed below [41]:

M_r	186.04
Density	1.49 g/cm^3
mp	173 °C
bp (at 102.3 kPa)	249 °C
Triple point	183 °C
Vapor pressure	
40 °C	0.0066 kPa
100 °C	0.34 kPa
Heat of fusion (at 175 °C)	17.8 kJ/mol
Heat of vaporization (at 175 °C)	47.2 kJ/mol
Heat of sublimation (at 25 °C)	70.2 kJ/mol
Start of decomposition	465 °C

Ferrocene is readily soluble in all hydrocarbon and hydrocarbon – oxygenate fuel blends and does not alter specified gasoline properties except for octane numbers.

Chemical Properties. Ferrocene is resistant to water, air, light, and heat.

Production. The modern electrochemical synthesis of ferrocene consists of two stages:

1) Electrochemical step (NaBr added as conductivity enhancer)

$$Fe + 2\,C_2H_5OH \rightarrow Fe(OC_2H_5)_2 + H_2$$

2) Chemical conversion

$$Fe(OC_2H_5)_2 + 2\,C_5H_6 \rightarrow Fe(C_5H_5)_2 + 2\,C_2H_5OH$$

Total:

$$Fe + 2\,C_5H_6 \rightarrow Fe\,(C_5H_5)_2 + H_2$$

In the *first stage*, metallic iron is oxidized anodically in ethanol to iron(II)ethoxide. At the cathode, the acidic protons of ethanol are reduced and form gaseous hydrogen which evolves out of the liquid. The iron(II)ethoxide is sparingly soluble and precipitates on the rotating cathode. A fixed scraper separates the iron(II)-ethoxide from the cathode surface and suspends it into the liquid. In the *second stage* the ethoxide reacts with cyclopentadiene to form ferrocene and ethanol, which is recycled to the first stage. Ferrocene is filtered from the solution and purified by sublimation.

Octane Enhancement. The octane improvements depend–as in the case of other octane enhancers–on the ferrocene concentration and on the composition of the base gasoline. Figure 11 represents a compilation of octane measurements performed in about 50 different base gasolines with ferrocene concentrations up to 30 ppm [42]. The octane response of RON is higher than that of MON.

Figure 11. Ferrocene octane enhancement in unleaded gasolines

The composition of the different unleaded fuel grades tested was widely varied. The fuel blends included all major refinery components as well as available oxygenates within their maximum volumetric addition presently specified in Europe. Generally it was found that the lower the octane number of the base gasoline, the higher the octane gain. Several measurements of octane response versus concentration have shown that response is more pronounced in the low ferrocene concentration region and that levelling-off effects are obtained at higher concentrations.

Toxicology. The toxicological data of ferrocene are listed in Table 8.

Table 8. Toxicity data of ferrocene [40]

Test	Species	
	Rat	Mouse
Oral		
LD_{50}, mg/kg	1320	832
Intraperitoneal		
LD_{50}, mg/kg	500	335
Intravenous		
LD_{50}, mg/kg		178

1. Introduction

1.1. History

Crude oil or petroleum, and a limited number of oil derivatives such as asphalt, pitch, and naphtha have been known and sporadically used since medieval times in the Orient, Europe, and America. However, it was not until the 19th century that significant oil processing started.

The first commercial oil operations can be dated back to the 1850s, with production commencing in Russia, Romania, and the United States [1]. The first successfully purpose-drilled oil well in 1859 in Pennsylvania was the beginning of the modern oil industry, since it stimulated fast development in the search, production, and refining of oil.

Subsequently, small and simple oil refineries were built and operated in direct vicinity of the Pennsylvanian oil fields and on the east coast of the United States, where former coal distillation processes were modified for oil processing. These first distilling units worked in *batch operation* and produced a small number of oil fractions.

Batch distillation was later combined with a thermal cracking step in order to increase the distillate yield. In this crack distillation, the heavier part of the oil was heated further and cracked until coke remained as residue in the still. The lower sections of the vessels were equipped with fired heating tubes to improve heat transfer.

Important progress in oil processing was achieved in Russia with the *continuous crude distillation* process which was introduced in a refinery in Baku in 1875. The continuous principle worked with a battery of stills, arranged in series, with stepwise gravity overflow of the oil throughout the battery. The stills were heated up to successively increasing temperatures, so that each still could produce a distillate fraction corresponding to its temperature level. This continuous process system offered the possibility for mass production at reduced manpower requirements, and utilization of the residual heat for preheating the crude oil feed.

During the first five decades of oil refining the predominant product was kerosene (lamp oil), and only small amounts of other products, such as fuel oil, pitch, and lubricating oil, were marketable. The lubricating oils were produced by vacuum distillation (United States, in the 1870s) and steam distillation (Russia, in the 1880s). The lightest and heaviest fractions of the crude oil distillation, namely gasoline and residue, were not used at that time and had to be burnt.

From the beginning of the 20th century, a complete shift in product demand occurred because of the fast expansion of electricity and motorization. The availability of electricity greatly diminished the demand for lamp oil, whereas the increase in motor vehicles increased the need for gasoline, which soon became the priority product.

The increasing gasoline demand initiated the development of *thermal cracking processes*. The Burton process, which came into operation ca.

1912, produced up to 30 % of cracked gasoline from paraffinic gas oil feedstocks.

During World War I the requirements for a variety of oil products, in particular gasoline and fuel oils, rose dramatically, and the demand continued to increase in the 1920s and 1930s. Gasoline again showed the highest growth rates. In the same period the bitumens (asphalts) (→ Asphalt and Bitumen) became a desired and important product group, owing to the expansion of road construction.

By the mid 1920s a new generation of *improved thermal cracking processes* emerged, of which the Dubbs process gained supreme importance. The gas oil or residue feed was heated in a cracking furnace, and the cracking reactions were completed in reaction chambers in which coke was formed as residual product. The yield of cracked gasoline could be as high as 50 %. However, with the advent of the *Houdry catalytic cracking process* during the second half of the 1930s, the thermal cracking capacities were largely replaced by catalytic cracking units which took the lead in gasoline production in the next two decades.

The catalytic cracking process proved that the octane quality of cracked gasolines that contain unsaturated hydrocarbons was superior to that of distilled (straight-run) gasolines. Hence, the straight-run naphthas were increasingly processed in *thermal reformers* at high cracking temperatures, to add a higher portion of unsaturated hydrocarbons to the motor gasoline.

In the late 1930s the first *catalytic reforming processes* were developed with improved gasoline quality by simultaneous desulfurization and increase in octane number. These *hydroforming* processes used molybdenum-on-alumina catalysts in the presence of hydrogen at high temperature and pressure.

With the introduction of *platinum catalysts* in the late 1940s, the catalytic reforming process was greatly improved: high quality gasolines were produced in higher yields, and hydrogen was formed as byproduct.

A desulfurization step (*hydrotreating*) was installed upstream of the reformer, using cobalt – molybdenum catalysts and hydrogen in order to remove sulfur from the gasoline feedstock. Sulfur would otherwise poison the noble metal catalyst in the reforming process. Owing to their quality and yield advantages, catalytic reforming units replaced the thermal reforming capacities in a relatively short period of time.

In the 1930s the United States and the Soviet Union were the main oil producers and supplied sufficient gasoline products for their own needs. The consumer countries in the rest of the world had to rely on the oil supplies from a number of producing countries, chiefly from South and Central America (Venezuela, Mexico) and the Middle East (Iraq, Saudi Arabia).

The largest expansion of the oil industry took place within the three decades after World War II. Between 1950 and 1980, a fivefold increase in oil demand occurred worldwide. The formation of political and economic blocs in "eastern" and "western" hemispheres and the foundation of the OPEC (Organization of the Petroleum Exporting Countries) in 1960 were significant for international oil trade and distribution.

Oil refining underwent a rapid development initially in the highly industrialized regions of North America, Western and Eastern Europe, Eastern Asia, and Australia, and later, in the wake of increasing populations and energy demands, also in many developing countries in Latin America, Africa, and Asia. Finally, large refinery plants were also built in the OPEC countries for the export of products at the expense of crude oil exports.

The two worldwide crude oil price increases in 1973 – 1974 and 1979 – 1980 prompted changes in oil consumption, which caused the oil industry to develop processes with increased yields and a reduction of refinery capacities, especially in North America and Western Europe. The refining structures became more complex with the installation of higher capacities of residue conversion processes, such as *hydrocracking*, which increased yields of transportation fuels while crude oil consumption could be reduced.

1.2. General Aspects of Oil Refining

Crude oils are complex mixtures of a multitude of – mostly hydrocarbon-type – constituents with a wide variety of properties, hence they cannot be directly used for industrial or commercial applications. Therefore, crude oils must be worked up in a refinery by suitable processes to produce an assortment of products which can

be marketed according to certain quality requirements.

These products are predominantly used as transportation fuels (gasolines, kerosene, diesel) and for heating purposes (LPG, fuel oils), but also as feedstocks for the petrochemical industry (naphtha, LPG) and special manufacturing routes (lubricating oils, greases, bitumen), as well as specialty products (solvents, wax, coke). All these products consist of hydrocarbon mixtures, and there are only few materials that are produced as individual chemical compounds, e.g., propane, sulfur, or benzene – toluene – xylene (BTX) aromatics.

The crude oils are usually transported by tankers and/or pipelines to the refinery site, and stored in tanks before being processed. Refineries were preferably built in coastal regions near industrial consumer centers, but from the late 1950s on, they were also built in inland regions for area-oriented supplies. In the 1970s and 1980s large refinery complexes have also been erected on the coasts of oil exporting regions.

The processing structure of a refinery depends on the market requirements for the products to be sold and on the available type(s) of crude oil. Both factors must be considered to avoid excessive production of unmarketable or otherwise undesirable product(s) and to determine the refinery integration. Typical integrated refinery structures are dealt with in Chapter 5.

Modern refineries are operated continuously and with a high degree of automation. The processing capacities are high compared with other chemical industries. A medium-sized refinery may have a crude capacity of 10 000 t per day [corresponding to ca. 73 000 barrels (bbl) per day]. The crude distillation determines the refinery capacity. A breakdown of worldwide refining capacities in 1997/1998 is given in Table 1. In this table the countries with oil refining capacities are allocated to seven world regions: North America, Latin America, Europe (excluding Former Soviet Union), Former Soviet Union (FSU), Asia (excluding FSU), and Australia/Oceania.

A selection of the following process units (see next page) may be found in modern integrated refineries, depending on the process routes to be installed.

Table 1. World oil refining capacities 1997/1998, capacity figures are given in 10^6 t/a (derived from [2])

Country/region	Refining capacity, 10^6 t/a

Figure 1. Aerial photograph of a refining complex

Process	Purpose/Products
Crude distillation	crude oil fractionation into gas, gasoline, kerosene, gas oils, and atmospheric residue
Crude desalter (as required)	crude oil desalination
Vacuum distillation	separation of atmospheric residue into vacuum gas oils and vacuum residue
Naphtha hydrotreater	gasoline desulfurization
Kerosene hydrotreater	kerosene desulfurization
Gas oil hydrodesulfurizer	diesel and light heating oil desulfurization
Catalytic reformer	conversion of desulfurized gasoline into high-octane gasoline, LPG, hydrogen, and fuel gas
Gas treating and separation	purification of LPG, fuel gas (e.g., removal of hydrogen sulfide)
Catalytic cracker	conversion of vacuum gas oils or residues into fuel gas, LPG, gasoline, and gas oils
Visbreaker	thermal cracking of vacuum residue into fuel gas, gasoline, gas oil, and heavy fuel oil
Hydrocracker	conversion of vacuum gas oils or residues into fuel gas, gasoline, kerosene, and gas oils
Coker	thermal cracking of vacuum residue into fuel gas, gasoline, gas oil, and coke
Deasphalting	solvent extraction of vacuum residue for deasphalted oil and asphalt
Alkylation (C_3/C_4)	production of alkylate [1]
Polymerization (C_3/C_4)	production of polymerate [1]
Isomerization (C_5/C_6)	production of isomerate [1]
Aromatics plant	solvent extraction of high-octane reformate to produce BTX aromatics
Lubricating oil plant	extraction, dewaxing, and hydrofinishing of vacuum gas oils to produce lubricating oils
Bitumen blowing	oxidation of vacuum residue to bitumen grades
Sulfur recovery	conversion of hydrogen sulfide (from gas treating) into sulfur
Hydrogen plant	hydrogen manufacture

[1] Gasoline components

A photograph of a typical refining complex is shown in Figure 1.

2. Crude Oils and Products

2.1. Crude Oil Constituents

Crude oils are composed of a great variety of *hydrocarbons* (→ Hydrocarbons). Hydrocarbons with one to four carbon atoms (methane – butane) are gaseous at room temperature, hydrocarbons with more carbon atoms are liquid at room temperature (pentane, hexane, etc.). Hydrocarbons with more than seventeen carbon atoms per molecule are solid at room temperature as pure compounds, but these are usually dissolved in the liquid portion of the crude oil.

Three types of molecular structures are possible for hydrocarbons, i.e., straight-chain, branched-chain, and ring structures. Three possible structures of hexane are given as an example:

The higher and more complex hydrocarbon molecules consist of various combinations of these structures.

Saturated hydrocarbons are known as paraffins or alkanes (IUPAC name). They can be further classified in normal, iso-, and cycloalkanes. Cycloalkanes are also called naphthenes.

Unsaturated hydrocarbons (olefins or alkenes) are not normally contained in crude oils, but they are formed in various refining processes, particularly during cracking and dehydrogenation.

Crude oils also contain varying amounts of *aromatics*: simple aromatics such as benzene, condensed polynuclear aromatics, and aromatic ring systems with various paraffinic or olefinic side chains. Aromatics are also formed in various conversion processes.

There are also a number of nonhydrocarbons present in crude oils in relatively small concentrations. Examples are sulfur-, nitrogen-, and oxygen-containing compounds. Metal compounds, e.g., vanadium, iron, and nickel compounds occur in trace quantities.

Most of these components are undesirable because they either cause problems in crude oil processing or deteriorate product qualities. Therefore, they must be removed by suitable refining processes.

Sulfur compounds such as hydrogen sulfide, thiols (mercaptans), sulfides (thioethers), disulfides, polysulfides, and thiophenes, may cause corrosion of equipment, bad odor in products, and catalyst poisoning. Moreover, sulfur compounds in fuel products contribute to air pollution by formation of sulfur dioxide and trioxide when burnt, and thus have to be removed from oil products as far as possible. This is achieved by means of desulfurization processes and subsequent conversion of hydrogen sulfide to elemental sulfur as a marketable product.

Nitrogen compounds are more stable than sulfur compounds, and are only partially removed in the desulfurization processes. Specific denitrogenation may be desirable for catalytic cracking or hydrocracking feedstocks to avoid catalyst deterioration, and for fuel oils to reduce formation of nitrogen oxides in burning.

Oxygen compounds may be present as naphthenic acids and phenols. *Naphthenic acids* (mostly mono- or dicyclic cycloalkane carboxylic acids, e.g., cyclopentane carboxylic acid) are constituents of naphthenic crude oils. Being corrosive, they have to be removed from crude oils or distillates by alkali extraction in the distillation process. The separated naphthenic acids are marketed as acidic extractants for metals; naphthenates are used as metallic soaps.

Phenols (which cause odor problems) are formed and recovered in the catalytic cracking process.

Metals act as catalyst poisons and can be removed by a demetallization step upstream of catalytic residue conversion processes. In catalytic cracking metal passivation additives are applied where buildup of vanadium and nickel in the catalyst bed poses a problem.

2.2. Classification of Crude Oils

The quality of crude oils can be classified either according to hydrocarbon type, product fractions, or sulfur content. Although rather unspecific, these classification methods are useful for the selection of suitable crude oils for given refining structures and product demand patterns.

Classification According to Hydrocarbon Types.

Paraffin-based crude oils consist predominantly of paraffinic hydrocarbons. The low and medium molecular mass paraffins are suitable for all kinds of catalytic conversion into gasolines and middle distillates, and for chemical feedstocks. The high molecular mass paraffins are usually good raw materials for the manufacture of lubricating oils and paraffin waxes.

Naphthene-based crude oils mainly contain naphthenic, aromatic, and asphaltic hydrocarbons. The low and medium molecular mass ranges can be used for the production of valuable gasoline components, solvents, and feedstocks for aromatics manufacture. The high molecular mass ranges find use in special types of lubricants and in the production of bitumen.

Mixed-based crude oils have a more or less even distribution of paraffinic and naphthenic/aromatic hydrocarbons over all ranges of molecular mass. They constitute the largest class of crudes.

Classification According to Product Fractions. This characterization commonly distinguishes between "light", "medium", and "heavy" crudes, i.e., the classification is based on the proportions of distillates and residue. This quality distinction takes into account the wide compositional varieties of crude oil fractionation. The percentages of the main fractions of some well-known crudes are listed in Table 2.

Table 2. Yields of distillation fractions of selected crude oils

Type of crude, origin	Gas, LPG, vol %	Gasoline, vol %	Kerosene, vol %	Gas oil, vol %	Atmospheric residue, vol %

Alaska, United States	0.5	13.5	11.5	21.5	53
Tia Juana, Venezuela	–	1.5	3.5	14.5	80.5

The *light crudes* which are rich in gasoline and gas oil are, for example, represented by Norwegian and Nigerian crudes with correspondingly low residue contents. The *heavy crudes* such as Venezuelan or Alaskan crude oils contain relatively small amounts of distillates but high portions of residue, thus requiring higher conversion capacities than lighter crudes. A *middle group*, e.g., Saudi Arabian or British crude, has an advantageous (i.e., well-balanced) distribution of fractions.

Classification based on percentages of product fractions may assist in the crude selection for a refinery according to product priorities, taking into consideration the refinery conversion structure.

The lighter crude types are usually more expensive than those with high residual portions.

Classification According to Sulfur Content. An important crude property is the sulfur concentration which determines the processing complexity of a refinery to a considerable extent. The higher the sulfur content in the crude and its various fractions, the stronger is the need for adequate desulfurization and sulfur recovery capacities. Table 3 lists the sulfur contents of a number of crudes and their residues.

Table 3. Sulfur contents of selected crude oils and their atmospheric residues

Type of crude, origin	Sulfur content of crude, wt %	Sulfur content of atmospheric residue, wt %
Ekofisk, Norway	0.1	0.3
Forties, United Kingdom	0.3	0.6
Es-Sider, Libya	0.5	0.9
Alaska, United States	1.0	1.5
West Siberia, Russia	1.5	2.6
Isthmus, Mexico	1.6	3.0
Kuwait, Kuwait	2.5	3.8
Arabian light, Saudi Arabia	3.0	4.5

The sulfur content is an important factor worldwide in pricing crude oil; the group of low-sulfur crudes with <1 wt % of sulfur constitute the most desirable but generally most expensive qualities. Crude oils with 1.0 – 1.5 wt % of sulfur are classified as medium-sulfur, and those having above 1.5 wt % as high-sulfur crudes.

2.3. Oil Products

In general ca. 80 – 90 % of oil products are used as transportation and combustion fuels. The most important products, their applications, and some typical specifiactions are briefly described below.

2.3.1. Gas Fuels

1) *Refinery gas* consists of gas streams that contain mostly methane and ethane which are burnt as fuel gas in refinery furnaces.
2) *Liquefied petroleum gas* (LPG) (→ Liquefied Petroleum Gas) consists of propane, butanes, and mixtures thereof. It is used for heating purposes and special products. In some countries, e.g., Japan, the United States, and The Netherlands, LPG is also used to a considerable extent as motor fuel. LPG specifications are based on national standards. The specified characteristics mainly concern vapor pressure, density, and contents of impu-

rities (e.g., elemental sulfur, COS sulfur, hydrogen sulfide, vaporization residue, hydrogen, nitrogen, oxygen, and methane).

2.3.2. Liquid Fuels

Motor gasolines are blended products with a boiling range between 40 and 200 °C and are used for motor car engines (spark-ignition motors) (→ Automotive Fuels). Typical gasoline components are light and heavy cracker and reformer gasolines, alkylates, isomerates, polymerates, pyrolysis gasoline, and LPG. Alcohols and ethers are added as nonhydrocarbon products. Gasolines have to comply with a large variety of specifications, among which the knock rating (octane number), volatility, boiling characteristics, density, oxidation stability, and lead contents are of prime importance. Typical specifications for unleaded gasolines (regular and premium grades, EN 228) are:

Regular grade	
Knock ratings	
RON	these ratings are specified according to national standards (e.g., for Germany RON min. 91.0, MON min. 82.5)
MON	
Density (at 15 °C)	min. 725 kg/m^3 max. 780 kg/m^3
Vapor pressure	specified according to applicable volatility classes (table in EN 228)
Boiling characteristics	
Lead content	max. 0.013 g/L
Benzene content	max. 5.0 vol %
Sulfur content	max. 0.05 mass %
Oxidation stability	min. 360 min
Premium grade	
Knock ratings	
RON	min. 95.0
MON	min. 85.0
Density (at 15 °C)	min. 725 kg/m^3 max. 780 kg/m^3
Vapor pressure	specified according to applicable volatility classes (table in EN 228)
Boiling characteristics	
Lead content	max. 0.013 g/L
Benzene content	max. 5.0 vol %
Sulfur content	max. 0.05 mass %
Oxidation stability	min. 360 min

The maximum addition rates of oxygen-containing gasoline components (*oxygenates*, e.g., methanol, ethanol, isopropanol, 2–methylpropanol, and ethers) are specified by relevant national standards.

Kerosenes are tailor-made products in the boiling range between 150 and 250 °C.

Lamp kerosene (lighting oil, cooking oil) has the longest tradition of oil products and is still widely used in most areas of the world. Smoke point, flash point, and volatility are important specifications.

Jet fuels, or aviation turbine fuels (→ Aviation Turbine Fuels), which are used worldwide in commercial aviation, have to undergo stringent quality screening. Control of density, freezing characteristics, viscosity, thermal stability, conductivity, corrosion behavior, water content, aromatics, and sulfur content is essential. A selection of Jet A-1 specifications is given below (based on relevant ASTM methods) (see also → Aviation Turbine Fuels, Chap. 2.1.).

Density (at 15 °C)	775 – 840 kg/m^3
Distillation	
10 vol % recovered at	max. 205 °C
End point	max. 300 °C
Residue/loss	max. 1.5 vol % each
Flash point	min. 38 °C
Acid number	max. 0.015 mg KOH/g
Aromatics content	max. 22.0 vol %
Mercaptan sulfur content	max. 0.003 mass %
Sulfur content	max. 0.30 mass %
Freezing point	max. − 47 °C
Viscosity (at − 20 °C)	max. 8.0 mm^2/s
Specific energy	min. 42.8 MJ/kg
Smoke point	min. 25 mm
Copper corrosion (2 h/100 °C)	max. 1
Thermal stability (at 260 °C)	
Tube depositrating	< 3
Filter pressure drop	max. 25.0 mm Hg
Electrical conductivity	50 – 450 pS/m

Further specifications are given for contaminants and additives. Additional domestic specifications have to be observed in various countries.

Gas oils are light and heavy gas oil fractions, and blends thereof, from straight-run and cracked origins, in a boiling range between 200 and 350 °C. The gas oils are predominantly used as automotive diesel fuels (→ Automotive Fuels) and as domestic heating fuels (→ Heating Oil). Typical specifications for automotive diesel fuel and domestic fuel oil are listed below.

Automotive diesel fuel (specifications for moderate climate according to EN 590):

Density (at 15 °C)	min. 820 kg/m^3 max. 860 kg/m^3
Kinematic viscosity (at 40 °C)	min. 2.0 mm^2/s max. 4.5 mm^2/s

Distillation	
Recovery at 250 °C	max. 65 vol %
Recovery at 350 °C	min. 85 vol %
Recovery at 370 °C	min. 95 vol %
Cetane number	min. 49
Cetane index	min. 46
Flash point	min. 55 °C
Cold filtration test (CFPP)	classified between + 5 °C and − 20 °C for regional specifications and interseasonal qualities
Sulfur content	max. 0.20 mass %
Water content	max. 200 mg/kg
Ash content	max. 0.01 mass %
Carbon residue	max. 0.30 mass %
Oxidation stability	max. 25 g/m^3

Domestic fuel oil (specifications for extra light heating oil according to German standard DIN 51603-1 as an example):

Density (at 15 °C)	max. 860 kg/m^3
Kinematic viscosity (at 20 °C)	max. 6.0 mm^2/s
Distillation	
Recovery at 250 °C	max. 65 vol %
Recovery at 350 °C	min. 85 vol %
Flash point	min. 55 °C
Pour point	max. − 9 °C
Calorific value (net)	min. 42.6 MJ/kg
Carbon residue	max. 0.5 mass %
Sulfur content	max. 0.20 mass %
Water content	max. 200 mg/kg
Ash content	max. 0.01 mass %

Heavy fuel oils consist of various grades of mixtures of residual oils from distilling and conversion processes (→ Heating Oil). High density, viscosity, or sulfur content of very heavy oils can be corrected by blending with gas oils. Marine fuels (bunker fuels), power stations and industrial furnaces are major outlets for heavy fuel oils. Specifications of various grades of marine distillative fuels and marine residual fuels are given in ISO 8217.

Important characteristics are density, kinematic viscosity, flash point, pour point (mostly defined for summer and winter qualities), carbon residue, ash, water, and sulfur content, and sediments.

2.3.3. Nonfuel Applications

Nonfuel applications are as follows:

1) LPG and light naphtha fractions are used as feedstocks for the petrochemical industry.
2) Special boiling-range naphthas are produced for various grades of solvents used in the chemical and pharmaceutical industry.
3) Paraffin waxes are used in the paper, chemical, and textile industries, and in medicine.
4) Heavy distillates are employed for the production of lubricants and greases (→ Lubricants and Related Products).
5) Heavy residues are raw materials for the manufacture of road bitumens and asphalts (→ Asphalt and Bitumen).
6) Petroleum coke (→ Petroleum Coke) and high-grade coke are used for various industrial applications and electrode manufacture, respectively.

3. Oil Refining Processes

3.1. Crude Oil Distillation

The fractional atmospheric distillation of crude oil is performed in continuously operated fractionation columns. The necessary heat for the fractionation is introduced through fired tube furnaces. A great variety of trays or decks are applied as column internals. Examples are grid trays, bubble cap trays, box trays, and valve trays which have been developed with the aim of improving the stage-to-stage vapor – liquid separation in the columns. Special types of trays are designed for distributing the incoming product and for collecting the draw-off product.

Figure 2 (see next page) shows the temperature – yield diagram for the boiling curves of four fractions of a crude fractionation, i.e., light and heavy gasoline (naphtha), kerosene, and gas oil. Their boiling ranges between the 5 and 95 vol % yield points are ca. 45 – 105 °C, 110 – 155 °C, 165 – 260 °C, and 240 – 360 °C, respectively. In this example there is obviously a boiling "overlap" between kerosene and gas oil; boiling "gaps" exist between heavy gasoline and kerosene and between the two gasoline fractions. The overlap reveals a rather inferior fractionation, whereas the gaps indicate good fractionation in the respective column sections.

Hydrocarbon fractions boiling above 360 °C should not be recovered by atmospheric distillation because cracking of the heavier products starts above this temperature. Therefore, the atmospheric residue must be subjected to vacuum

distillation. Under the reduced pressure in vacuum columns, the higher-boiling oil fractions can be vaporized under similar temperature conditions as in the gas oil section of atmospheric fractionation. The final boiling point of a full-range vacuum gas oil (feedstock for catalytic cracker) would correspond to ca. 550 °C at atmospheric conditions.

3.1.1. Atmospheric Distillation

Atmospheric distillation is the first step in crude oil processing. The crude oil is separated into fractions of different boiling ranges. The distillation columns are usually operated continuously.

Figure 2. Temperature – yield diagram of ASTM boiling ranges of crude oil fractions

Figure 4. Crude preheat train of a crude oil distilling unit

Some major properties of the final products are established by the fractionation, for example, the boiling ranges of automotive fuels, the flash points and viscosities of lubricating oils, or the penetration (viscosity) of heavy fuel oil.

Modern fractionation columns are designed to yield one or several side streams in addition to a top and a bottom fraction. Figure 3 shows a typical atmospheric crude oil distillation unit, combined with a crude desalter and vacuum distillation. The crude oil is pumped from storage through the desalter (see Section 3.1.3) and is preheated in a series of heat exchangers (see Fig. 4) to ca. 220 – 250 °C before entering the furnace (crude heater). Here it is heated up to the required column inlet temperature which is in the range of 360 – 380 °C. In the main fractionator the partially vaporized crude is separated into a top product, three side products, and a bottom product.

Top Product. The column top vapors are condensed and separated into gas and full-range gasoline in the overhead accumulator. Part of the *liquid gasoline* is pumped back to the column as top reflux; the remainder is fed to the naphtha hydrotreater (see Section 3.3.1). The *gas stream* (uncondensable $C_1 - C_4$ hydrocarbons and H_2S) from the overhead accumulator is processed further in a gas treatment plant.

Process water originating from the stripping steam that is applied to the fractionator and stripper columns, is withdrawn from the sump of the overhead accumulator and treated further in a wastewater treatment plant.

Side Streams. The side streams comprising of the middle distillates, i.e., kerosene, light and heavy gas oil, are transferred to their respective stripper columns where the lighter constituents are stripped off by injection of superheated steam.

The *kerosene stream* from the stripper column is pumped off either to a hydrotreater for the production of jet fuel, or via a heat exchanger and cooler directly to storage if it is to be used as a blending component for diesel fuel.

Figure 5. Vacuum flasher for catalytic cracker feedstock
a) Residue heater; b) Vacuum flasher; c) Vacuum system

The *light gas oil* fraction is also pumped to storage via a heat exchanger and cooler and is used for diesel and light heating oil blending.

The *heavy gas oil* fraction is fed to the hydrodesulfurization unit when it is used for the production of diesel fuel and light heating oil, or it is (partially) pumped via a heat exchanger and cooler to storage for direct blending.

One or more liquid side streams of the main fractionator column can be used as circulating reflux (CR). These circulation streams deliver heat to the crude oil via heat exchangers and contribute to the fractionation sharpness by returning the cooled product back to the column.

Bottom Product. The bottom product, namely atmospheric residue, can be supplied to a vacuum fractionator for the production of lubricating oil fractions (see Fig. 3) or to a vacuum flasher for the preparation of catalytic cracker feedstock (see Section 3.1.2). Alternatively, the residue can serve as feedstock for a variety of other cracking processes, e.g., thermal and catalytic cracking, hydrocracking, or hydroconversion.

3.1.2. Vacuum Distillation

Generally two versions of vacuum distillation are applied – the vacuum flasher and the vacuum fractionator.

The *vacuum flasher* has a relatively simple design with a limited number of trays, because it serves only for the separation of atmospheric residue into a wide-boiling vacuum gas oil that is used as catalytic cracker (CC) feedstock and a vacuum residue for bitumen manufacture or visbreaker feed. No specific separation sharpness is required for preparing the CC feed. Figure 5 shows a typical vacuum flasher. The vacuum is produced by a set of steam ejectors as shown in Figure 6.

Figure 6. Vacuum ejector system
a) Vacuum column; b) Steam ejectors; c) Condensers

The *vacuum fractionator* is essential for the preparation of lubricating oil fractions. The vacuum fractionator separates the vacuum gas oil portion of the atmospheric residue into light and heavy spindle oils, light and heavy machine oils, and cylinder oil (→ Lubricants and Related Products). To achieve this high degree of fractionation the vacuum distilling section is often splitinto two fractionator columns.

3.1.3. Crude Oil Desalting

Although crude oils delivered from production fields are desalted, a small portion of water and salt always remains in the crudes which reach the refiners. Salt contents (sodium, calcium, and magnesium chlorides and sulfates) can have detrimental and costly effects on oil processing equipment. Examples are corrosion in the fractionator overhead system due to the formation of hydrochloric acid; erosion or sedimentation of salt in lines, furnace tubes, pumps,

Figure 7. Electrical crude oil desalter
a) Chemical injection; b) Mixing valve; c) Crude desalter; d) Crude booster pump

and valves; and impaired heat transfer due to salt deposits in heat exchangers. It is therefore advisable to install a desalting unit in the crude feed line to the distillation unit.

The most common desalting unit is the *electrical desalter.* An electrical field is applied in the desalting vessel which breaks up saltwater – oil emulsions by coalescence of the water droplets and segregation of the water from the oil phase. A typical electrical desalter is shown in Figure 7.

3.2. Catalytic Cracking (Cat Cracking)

The commissioning of the first catalytic cracking plant in 1936 (Houdry process, United States) initiated a new era in petroleum refining. Until then, thermal cracking of distillates had been the governing conversion process, the role of which was taken over very soon by catalytic cracking. This development was particularly influenced by the increased demand for high-quality transportation fuels during World War II.

Four major advantages of catalytic over thermal cracking supported this development:

1) Lower production of C_1 and C_2 hydrocarbons to the credit of higher yields of C_3 and C_4 hydrocarbons (Fig. 8), which can be used for the manufacture of isoparaffins for motor gasoline via alkylation and polymerization processes.
2) Lower cracking temperatures which result in a lower production of diolefins, thus improving the oxidation stability of the gasoline fractions.
3) Higher octane ratings of gasoline by increased formation of branched alkanes, naphthenes (cycloalkanes) and aromatics.
4) Higher cracking reaction rates, allowing smaller dimensioning of plant equipment.

Figure 8. Product distribution of $C_1 - C_7$ hydrocarbons from thermally and catalytically cracked C_{16} key component [3]

The conversion reactions of oil distillates in the catalytic cracking process occur mainly in the vapor phase at elevated temperatures in the presence of a cracking catalyst (originally of the montmorillonite type, currently synthetic crystalline zeolites). The cracking reactions occuring at the active sites of the catalysts proceed via a carbenium ion ion mechanism that predominantly effects the formation of olefins, isomeric components, and aromatics (the latter via intermediate formation of cycloolefins. The formation of low-boiling olefins, branched alkanes, and aromatics favors the production of gasolines with high octane levels.

A considerable portion of the cracker feedstock is converted to gaseous components which are separated in a gas plant into fuel gas (containing hydrogen, methane, ethane, ethylene, and hydrogen sulfide) and LPG fractions, i.e., propane – propene and butane – butene. After treatment, these LPG streams are predominantly

processed in alkylation and polymerization units for the production of high-octane gasoline components (see Sections 3.7.1, 3.7.2). Part of the propane and butanes is also used for LPG sales or as chemical feedstock.

The *cracked gasoline* (research octane number > 90) must be treated to remove undesirable impurities, such as hydrogen sulfide, mercaptans, phenols, and nitrogen compounds, because they are responsible for unacceptable odor and corrosion.

The *middle distillates*, i.e., light and heavy gas oils, serve as blending stocks for light heating and diesel oils and heavy fuel oil, respectively. The cat cracked gas oils are traditionally referred to as light and heavy "cycle oils" since they have been widely used as recycle products to maximize gasoline production in the process.

An important byproduct of catalytic cracking is coke which originates from heavy carbonaceous material. Coke forms deposits on the catalyst particles and thus impairs catalyst activity. Therefore, the process must include a regeneration step where the carbon is burnt off the catalyst for reactivation before entering the reaction step.

Distillate fractions have been used for about four decades as catalytic cracking feedstocks – chiefly *heavy gas oils* (vacuum gas oils) and to some extent *deasphalted oils*. Residual materials could not be processed because of their heavy metals content (nickel and vanadium) since this caused irreversible poisoning of the cracking catalysts. In addition, the metals and the asphaltene contents of the residues led to increased coke deposition on the catalysts. However, the introduction of metal-resistant catalysts and installation of feed pretreatment facilities since the mid 1970s have also made atmospheric residues accessible for catalytic cracking processes (see Section 3.6.4.2).

The development of catalytic cracking units gave rise to many improvements to the process within a relatively short time span. The first Houdry design was a fixed-bed process which required cyclic operation (switching of a series of vessels between reaction and regeneration steps). A new continuous type of process, the Thermofor Catalytic Cracking (TCC), then emerged. This process version used a furnace (Thermofor kiln) as regenerator for coke burning, and mechanical catalyst transport by elevators between reactor and furnace and vice versa. This moving-bed system was later replaced by gas-flow, and even later by gas-lift transport.

The introduction of powdered catalyst types gave way for the development of fluid-bed catalytic cracking (FCC) in 1942 (United States). Currently, FCC represents the most commonly applied catalytic cracking process. In a lifting gas stream the catalyst powder behaves like a fluid and can be transported in fluidized form through the system. Figure 9 shows the principle of an FCC process.

The catalyst flowing down from the regenerator (c) is combined with feed and steam, lifted up through the riser (d) into the reactor (a), where it is fluidized by hydrocarbon vapors. The catalyst then flows down via the stripper (b) to the regenerator, where it is fluidized by combustion gases.

Significant improvements in the quality of the cracking catalyst were also achieved. The change from the natural clay materials (montmorillonite), which were originally used, to synthetic amorphous silica – alumina catalysts in the 1940s and the introduction of synthetic crystalline zeolites in the 1960s produced remarkable gains in activity, stability, and selectivity of the catalysts. The addition of highly active zeolitic material to the silica – alumina catalysts resulted in a strong selectivity gain, i.e., increased yields of gasoline and less gas production.

Process Description. The flow diagram of a typical FCC process is shown in Figure 9. Hot catalytic cracker feed and dispersion steam enter the process at the riser foot (d) where they are mixed with the hot reactivated catalyst flowing down the regenerator standpipe (e_1). The feed is vaporized by the hot catalyst, and the mixture is lifted up the riser into the reactor (a), where the catalyst is segregated from the vapors. The cracking reactions usually start in the riser and are completed in the reactor. The vapors (cracked products) pass through cyclone separators to eliminate any remaining catalyst particles before they enter the fractionator section.

The catalyst in the reactor bed, now loaded with coke, drops into the stripper (b) where remaining hydrocarbons are stripped off by the addition of steam. From there the catalyst flows down via the stripper standpipe (e_2) into the regenerator bed (c), where the coke is burnt off

Figure 9. Typical FCC unit
a) Reactor; b) Stripper; c) Regenerator; d) Riser; e_1) Regenerator standpipe; e_2) Stripper standpipe; f) Cyclone vessel; g) Air blower; h) Flue gas expander; i) Waste-heat boiler; j) Fractionator; k) Absorber; l) Debutanizer; m) Depropanizer

by blowing combustion air into the vessel. The regenerated catalyst flows down through the regenerator standpipe to the riser foot. The flue gas leaves the regenerator via cyclone separators (f) to remove catalyst fines to avoid erosion of the internals of the downstream expander by catalyst particles. The gas then enters the heat recovery section (waste-heat boiler i).

The air blower (g) is driven by an expansion turbine (h) which utilizes the pressure difference of the flue gas. The heat of the flue gas is utilized in a waste-heat boiler for steam generation.

The fractionation and gas separation section consists of four columns – the fractionator (j), absorber (k), debutanizer (l), and depropanizer (m). The cracked products from the reactor are separated in these columns into fuel gas (C_2 and lighter), propane – propene, butane – butene, gasoline, light and heavy cycle oils (middle distillates), and slurry oil. The slurry oil contains some catalyst dust (carried over with the reactor product) and is normally recycled to the process.

The cracking sections of four different catalytic cracking processes are depicted in Figures 10, 11, 12, and 13 in more detail. The downstream fractionation and gas separation sections are not shown.

Fluid-Bed Catalytic Cracking Unit (Fig. 10) [4–7]. The partition of the regenerator vessel into a combustor and a disengaging section provides particularly efficient air – catalyst contact in the combustor section and low catalyst loadings in the regenerator cyclones.

Figure 10. Fluid-bed catalytic cracking

Riser Reactor FCC (Fig. 11) [5–9]. The cracking reactions proceed to completion in the riser, whereas the reactor serves as a catalyst – product disengaging vessel. Special flexibility is given by the two feed inlets at different eleva-

tions on the riser, and by the possibility of rapid conversion changes between maximum gasoline and maximum gas oil operation.

Figure 11. Fluid-bed catalytic cracking with riser reactor
a) Riser reactor; b) Cyclone vessel; c) Stripper; d) Regenerator

Figures 12 and 13 show the *riser-bed* and *transfer line flexicrackers*, respectively [6–8]. The transfer line configuration is applied for operations that require a short reaction time. The cracking reactions are interrupted at the top of the transfer line where fast separation of catalyst and cracked products occurs.

3.3. Hydrotreating

Until the 1940s there was little incentive for the petroleum industry to improve product quality by means of hydrogen treatment. Since the early 1950s, however, several influences have triggered the development of various hydrotreating processes. The increased production of high-sulfur crude oils and consequently the need to remove sulfur compounds from oil fractions, more stringent product specifications because of environmental requirements, and the production of increased quantities of cracked material from conversion processes boosted the installation of adequate hydrotreating capacities in refineries. Hydrotreating plants represent the highest capacities of all secondary refining processes worldwide.

The most important function of hydrotreating is the removal of sulfur components (hydrodesulfurization, HDS) by reaction with hydrogen in the presence of a suitable catalyst, to form hydrogen sulfide. Hydrogen sulfide is removed from the process gas stream using a solvent (e.g., amine) wash and is then converted into elemental sulfur in a Claus plant.

Hydrotreating processes are applied to achieve the following objectives:

1) Removal of sulfur, nitrogen, oxygen, and arsenic compounds from *reformer feedstocks* (naphthas) to prevent poisoning of the plat-

Figure 12. Flexicracking with riser-bed
a) Riser; b) Reactor; c) Stripper; d) Regenerator

Figure 13. Flexicracking with transfer line reactor
a) Transfer line reactor; b) Cyclone vessel – stripper; c) Regenerator

inum catalysts in the reformers. Hydrogenation of the unsaturated hydrocarbons of cracked naphthas to minimize coking of the reformer catalysts.

2) Increase in the thermal stability of *jet fuels*. Additionally, an improvement of the smoke point can be aimed at by (partial) hydrogenation of aromatics.
3) Removal of sulfur compounds from *middle distillates* (gas oils) to achieve blending qualities for diesel fuels and light heating oil. Unsaturated hydrocarbons in cracked gas oils are hydrogenated to improve the color stability and reduce the coking tendency of the products.
4) Removal of sulfur, nitrogen, and metal compounds from *catalytic cracking feedstocks* (vacuum gas oils, atmospheric residues) to limit the catalyst deactivation by nitrogen and metals, and to yield lower sulfur contents in the cracked products.
5) Reduction of the sulfur content of *heavy fuel oils*.
6) Hydrogenation of diolefins in *pyrolysis gasolines* (originating from ethylene production plants) to avoid the formation of gum which deteriorates the stability of these gasolines.
7) Improvement of odor, color, and oxidation stability of *lubricating oils* by hydrofinishing (mild hydrotreating). Dearomatization and removal of sulfur, nitrogen, and oxygen compounds by deep hydrogenation (high-pressure hydrotreating) of lubricating oils.

3.3.1. Distillate Hydrotreating

Two process types are used – the vapor-phase process for *hydrotreating of gasoline* (where the feed is vaporized in the reaction stage) and the trickle phase process for *hydrotreating and desulfurizing of straight-run middle distillates* or vacuum gas oils (where the major portion of the feed is liquid in the reaction stage).

The process scheme of both hydrotreating process types is identical. The feed stream is mixed with hydrogen-rich gas (usually fresh gas from catalytic reforming plus recycle gas from the hydrotreating process) and heated before it is passed through the catalyst bed in the reactor. The reactor product is cooled and separated into a gas and a liquid phase in two consecutive separation stages (high-pressure and low-pressure separators). The hydrogen-rich recycle gas from the high-pressure separator is recombined with the feed. The low-pressure off-gas which contains hydrogen sulfide is processed further in a gas treatment plant for H_2S removal. The liquid reactor product is stabilized in a debutanizer (gasoline hydrotreater) or stripper column (gas oil hydrodesulfurizer).

The two process types are shown schematically in Figure 14 (gasoline hydrotreating) and Figure 15 (gas oil hydrodesulfurizing), respectively. The catalyst types employed and the main operating criteria of distillate hydrotreatment processes are given in Table 4.

for highly unsaturated distillates

DPG – HT (Lummus Crest)
Pyrolysis distillate hydrogenation (IFP) [16]
Pyrolysis gasoline hydrogenation (BASF – VEBA)
Hydroisomerization/HPN IVB (Engelhard) [17].

Hydrotreating (hydrodesulfurization, hydrodemetallization) processes for residues are dealt with in Section 3.6.3.1.

3.3.2. Pyrolysis Gasoline Hydrotreating

This widely applied process can be used in a single-stage and a two-stage version, depending on the destination of the products. The feedstock is usually a pyrolysis gasoline from olefin plants (byproduct of naphtha steam cracking).

In the *first stage* the unsaturated and aromatics-rich material is selectively hydrotreated so that the conjugated double bonds of the diolefins and styrene are hydrogenated to produce a stable gasoline blending component. The main stability criteria are a reduction

Figure 16. Two-stage pyrolysis gasoline hydrotreater
a) First stage reactor; b) First stage separator; c) Depentanizer; d) Gasoline (heart cut) column; e) Second stage reactor; f) Second stage separator; g) Debutanizer

of the diene value (maleic anhydride value) from a range of 30 – 70 to 1 – 2, accompanied by a reduction of the bromine number from a range of 50 – 90 to 30 – 60. The induction period and potential gum content are also greatly reduced.

In the *second stage*, the first stage product or a fraction thereof ("heart cut") is hydrotreated further to achieve complete hydrogenation of the olefins and to accomplish desulfurization. Thus, an aromatics-rich product is yielded that is suitable for BTX recovery.

The main quality characteristics of the second stage are a reduction of the bromine number to < 1 and a sulfur removal from 1000 – 5000 ppm to < 1 ppm.

Figure 16 shows a typical two-stage unit.

3.4. Catalytic Reforming

3.4.1. Introduction

In the reforming processes, gasoline fractions (naphthas) with a low octane number are converted into a high-octane reformate, which is a major blending product for motor gasolines (→ Automotive Fuels, Chap. 4.). Valuable byproducts are hydrogen and liquefied petroleum gas.

The naphtha feedstocks for reformers can be of straight-run or cracked origin and usually have octane numbers of only 35 – 65. Therefore these products are unsuitable for direct gasoline blending. In addition, the reformer feedstocks must be pretreated to adjust them to the required specifications (e.g., sulfur content, see Section 3.3).

With the development and introduction of noble metal catalysts at the beginning of the 1950s, the catalytic process displaced other (mainly thermal) reforming processes, because the catalytic conversion produces higher liquid yields – together with higher octane numbers – and hydrogen. Catalytic reforming is chiefly based on the catalytic conversion of normal paraffins and cycloparaffins into aromatics and isoparaffins.

The catalysts applied are either of the single metal platinum-on-alumina type, or bimetallic species where platinum is used in combination with a second metal, e.g., rhenium. The bimetallic catalysts have a better operational stability, but are more sensitive toward poisoning (e.g., by sulfur) or deficient regeneration. The catalyst metal is dispersed on the porous carrier material (alumina). The various commercial catalyst types contain 0.25 – 0.8 wt % platinum and up to 1 wt % of a halogen, usually chlorine. In these "bifunctional" catalysts the metal promotes hydrogenation and dehydrogenation reactions, while the chlorine catalyzes isomerization and cracking reactions.

The chemical reaction mechanisms of the catalytic reforming process can be characterized as follows:

Dehydrogenation of C_6-Naphthenes to Aromatics. Example:

(1)

Conversion of methylcyclohexane into methylbenzene (toluene) with formation of 3 mol hydrogen per mole of converted hydrocarbon. The research octane numbers (RON) of methylcyclohexane and toluene are 75 and >100, respectively.

Dehydroisomerization of Alkyl-C_5-Naphthenes to Aromatics. Example:

(2a)

(2b)

In the first step, methylcyclopentane is isomerized to cyclohexane (2a).

According to Equation (1), cyclohexane is then dehydrogenated in a second step to form benzene with formation of 3 mol hydrogen (2b).

The RONs of methylcyclopentane, cyclohexane, and benzene are 91, 83, and >100, respectively.

Dehydrocyclization of Paraffins to Aromatics. Example:

(3)

n-octane is converted to 1,2-dimethylbenzene (*o*-xylene) under formation of 4 mol hydrogen. The RONs of these components are 0 and >100, respectively.

Hydrocracking of Paraffins and Naphthenes to Smaller Paraffin Molecules. Example:

$$CH_3CH_2CH_2CH_2CH_2CH_2CH_3 + H_2 \longrightarrow CH_3CH_2CH_3 + CH_3CH_2CH_2CH_3 \quad (4)$$

n-heptane is split into propane and normal butane under consumption of 1 mol hydrogen per mole of paraffin (2 mol hydrogen per mole of naphthene). This reaction does not affect the RON.

Isomerization of n–Paraffins to Isoparaffins. Example:

$$CH_3CH_2CH_2CH_2CH_3 \longrightarrow CH_3CH_2CH(CH_3)CH_3 \quad (5)$$

Conversion of n–pentane into isopentane. The respective RONs are 62 and 92.

Hydrogenation of Unsaturated Hydrocarbons. This reaction is also important because unsaturated hydrocarbons can act as coke precursors. Coke deposits would deactivate the catalyst.

The dehydrogenation reactions (Eq. 1) and (Eq. 3) are both endothermic and require appropriate heat input (i.e., 32 and 38 kJ/mol, respectively, at reforming temperature level). However, because the reaction in Equation (3) is considerably slower than that for Equation (1), higher temperatures must be applied to achieve the desired reaction rate. The isomerization reactions (Eq. 2a) and (Eq. 5) are thermally almost neutral, whereas the hydrocracking reaction (Eq. 4) is exothermic (ca. −16 kJ/mol at reforming temperature).

Dehydrogenating cyclization of paraffins (Eq. 3) and dehydrogenation of naphthenes (Eqs. 1 and 2b) are the largest contributers to octane quality improvement. The thermodynamic equilibria of these reactions are shifted to the side of the reaction products at low hydrogen partial pressures and a reforming temperature level of ca. 500 °C. The ring-enlarging isomerization of alkyl-C_5-naphthenes to C_6-naphthenes (Eq. 2a) involves a decrease in the octane number, but this effect is more than compensated by the subsequent aromatization step (Eq. 2b). The theoretically attainable equilibrium compositions of the isomerization of *n*- to isoparaffins according to Equation (5) are not be reached at the usual reforming conditions.

Hydrocracking (Eq. 4) is favored at high temperatures and high hydrogen partial pressures. These reactions are usually undesirable in catalytic reforming, because they consume hydrogen and produce gaseous hydrocarbons from liquid ones, thereby decreasing the yield of liquid reformate. This influence is illustrated in Figure 17, where reformate yields are related to reactor pressure at various octane levels.

At a given pressure, the octane number can be increased by applying higher reactor temperatures; this, however, results in yield loss by increased hydrocracking.

As a result, catalytic reformers should generally be operated at low pressure to achieve high liquid yields. However, the hydrogen par-

tial pressure must be high enough to avoid the formation of unsaturated compounds which may polymerize and cause increased coke deposition on the catalyst and hence its deactivation.

Figure 17. Reformate yield and reactor pressure at various octane levels

Catalytic reformers are usually available in three different versions, namely the semiregenerative, the fully regenerative, and the continuously regenerative reformer. Common to each process type is a reactor section and a product workup section. The fully and continuously regenerative process versions are also equipped with a catalyst regeneration section.

Various licensed reforming processes are described in [19] and [20]. Examples are Platforming (UOP), Magnaforming (Engelhard), Catalytic Reforming (IFP), Powerforming (Exxon), and Rheniforming (Chevron).

3.4.2. Semiregenerative Reformer

This conventional catalytic reforming process is shown in Figure 18. The plant has three or four reactors that are arranged side by side at ground level. After addition of hydrogen-rich recycle gas to the naphtha feed, the mixture is heated up in the charge – product heat exchanger (a) and brought to reaction temperature in the charge heater (b). The vaporized feed is then successively passed through the catalyst beds of the reactors (c, e, g). Between the reactors, makeup heat is provided in the intermediate heaters (d, f) to compensate for heat losses after each (endothermic) reaction step. The effluent from the last reactor is cooled in the heat exchanger and aftercooler (i). It is then separated in the product separator (h) into hydrogen-rich gas and liquid reaction product.

The H_2 gas is recompressed in the recycle gas compressor (k) and part is returned to the feed stream; the net H_2 "make gas" can be supplied to hydrogen-consuming units, such as hydrotreaters and hydrodesulfurizers.

Figure 18. Semiregenerative catalytic reformer
a) Charge – product heat exchanger; b) Charge heater; c) First reactor; d) First intermediate heater; e) Second reactor; f) Second intermediate heater; g) Third reactor; h) Product separator; i) Product cooler; j) Stabilizer; k) Recycle gas compressor

The liquid reactor product is fractionated in a stabilizer column (j) to separate the C_4 and lighter hydrocarbons from the reformate. The LPG stream (C_3 and C_4) is usually split in the LPG recovery plant for propane and butane production; (→ Liquefied Petroleum Gas, Chap. 3.); the stabilized reformate can be used directly for gasoline blending or is fractionated further into light and heavy gasoline components before blending.

The catalyst is gradually deactivated during the operation period; this can be counteracted by stepwise increase in the reactor temperatures to keep the product quality at the desired level. Once the recommended ultimate temperature is reached, the plant has to be shut down and the catalyst is regenerated. This procedure is usually performed in three successive steps, i.e., carbon burn-off, metal reduction, and metal redispersion. The plant is then restarted for its next operation period. When the operation cycles between regenerations become unacceptably short, the catalyst inventory is replaced by a new batch. The spent catalyst batch is worked up for metal recovery (platinum, rhenium).

3.4.3. Fully Regenerative Reformer

The fully-regenerative, or cyclic, reforming processes have been devised to increase the on-stream time of the reforming plants by introducing the "swing reactor" principle. A typical example is the Power forming process [21]. In a system of four reforming reactors, three reactors are on-stream, in the fourth the catalyst is regenerated. After completion of the regeneration, this reactor is brought on-stream, while another reactor is switched to regeneration. The cyclic process requires a complex switch system with automatically operated valves. However, with this method a continuity of operation at high reformation severities can be maintained over a long period, with catalyst lifetimes of up to five years.

3.4.4. Continuously Regenerative Reformer

Special moving-bed techniques were developed for reforming units with continuous catalyst regeneration. The *IFP catalytic reforming process* which employs a conventional side-by-side arrangement of reactors uses a system of lift pots to transport the moving catalyst in portions from the bottom of a reactor to the top section of the next reactor [22, 23]. The catalyst portions obtained from the last reactor are lifted to the regenerator, where carbon burn-off and reconditioning of the catalyst take place. The catalyst is then reinjected into the first reactor bed.

A sophisticated catalyst moving-bed system was realized in the UOP Platforming process as illustrated in Figure 19 [24, 25]. The reactors are

Figure 19. Continuously regenerative catalytic reformer (UOP Platforming)

a) Hydrogen heater; b) First-stage reactor (hydrotreating); c) Second-stage reactor (hydrocracking); d) High-pressure separator; e) Hydrogen compressor; f) Low-pressure separator; g) Fractionator

arranged in a "stacked" construction. The catalyst trickles through the system from the top of the first reactor to the bottom of the third reactor, where it is collected and lifted in portions to the regenerator section.

"Sluices" are incorporated in the catalyst transport system, i.e., the spent catalyst from the third reactor is depressurized, freed from hydrogen, and then lifted in an inert gas stream to the regenerator; in turn, the regenerated and reconditioned catalyst has to be flushed free of combustion gases and pressurized with hydrogen before it is reinjected to the first reactor.

With continuous catalyst reactivation severe reforming conditions can be applied to achieve RON values of well above 100 in the reformate product. Moreover, operation at low reaction pressures of 7 – 10 bar results in favorable yield structures, i.e., high reformate and hydrogen quantities at low gas production.

3.5. Hydrocracking

The hydrocracking (HC) process was developed to produce high yields of distillates with better qualities than can be obtained by fluid-bed catalytic cracking. Hydrocracking feedstocks are typically flashed distillates from vacuum distillation, from cat and thermal cracking, or deasphalted oils. Operating conditions in the reactor section of hydrocrackers are usually about 400 °C and 8 – 15 MPa. The reactions take place on metal sulfide catalysts in the presence of hydrogen. Major advantages of the process include the full-scale production of high-quality products, i.e., no low-grade fuel oil remains as residue, and the high flexibility towards product yields, i.e., possible gasoline maximization, or gasoline – kerosene, or kerosene – gas oil maximization.

Modern hydrocrackers are units with two reaction stages – a hydrogenation step for desulfurization, denitrogenation, and desoxygenation using cobalt – molybdenum catalysts, and a hydrocracking step using nickel – tungsten catalysts. After fractionation of the liquid reactor product into gas, naphthas, and middle distillate, the bottom product of the fractionator is fed to the hydrocracking reactor. A typical example of a two-stage hydrocracker is shown in Figure 20. Hydrocracking processes for treatment of residues ("hydroconversion" processes) are described in Section 3.6.3.2.

3.6. Residue Conversion Processes

3.6.1. Introduction

In the previous sections, the standard processes of refinery technology for refining of distillates were described. These are used to improve the product yields recovered from the crude as well as the quality of the individual products.

These steps include catalytic cracking and distillate hydroprocessing, i.e., processes whose main purpose is to increase the yield of light products from heavier crude fractions. These processes were developed and applied mainly in the United States, where the goal had been to achieve a high yield of motor gasoline as the

main product of crude oil processing. In Europe and most other consumer areas, however, the objective was a high yield of diesel fuels, and light and heavy fuel oils.

In addition to these distillate conversion processes, the conversion of residues and heavy crudes in the modern refinery is growing in importance as a comprehensive process step for several reasons [28, 29]:

1) Since the drastic oil price increase following the first oil crisis in 1973 (from ca. $ 2/bbl to more than $ 40/bbl with fluctuating but in the long term rising trends) there is a growing economic need to recover more light, high-value products from the crude oil barrel at the expense of the residue.
2) In many countries, heavy fuel oil has been substituted by other fuels, above all natural gas, because of high sulfur and heavy metal content of residual oils.
3) The oversupply of residues also increases when the crude to be processed becomes heavier, i.e., richer in residue over the medium and long term (African and North Sea oils contain ca. 10 wt % vacuum residue, oils from the Persian Gulf ca. 30 wt %, and Venezuelan heavy oils still higher proportions of vacuum residues), see Table 5.
4) Finally, even the heavy crudes can no longer be processed in a normal refinery without additional treatment because of the high proportions of impurities.

Table 5. Residue contents of typical crudes (in wt %)

	Atmospheric residue	Vacuum residue
Nigeria	34.0	8.2
Algeria	30.9	8.3
North Sea	39.7	13.1
Mexican Isthmus	47.6	19.2
Arabian light	47.6	19.2
Russia	40.9	17.5
Kuwait	53.5	27.2
Arabian heavy	56.6	31.9
Venezuelan heavy	75.6	43.0

Important criteria to be considered when selecting suitable heavy oil upgrading technologies are the range of crudes (i.e., the amount and quality of the residue to be processed), the product requirements (motor gasoline, diesel fuel, heating oil), and the flexibility of the refinery (existing structure, changing feed supply, and product demand).

The feedstocks for residue conversion plants are atmospheric and vacuum residues, heavy oils, bitumen, tar sands, and shale oils. The products or objectives of the conversion vary according to the starting material and the method of conversion. They range from processing a low-sulfur heavy fuel oil where only low yields of lighter products are aimed at, via maximization of the distillate yield to complete conversion of the residue. In the longer term the production of "synthetic crudes" (syncrudes) from tar sands and shale oils will gain in importance (Fig. 21).

3.6.2. Fundamentals of Residue Conversion and Process Options [30, 31]

The C:H ratio in the crude oil fractions increases with increasing molecular weight, i.e., the hydrogen deficiency of the residue (in comparison with lighter hydrocarbons) increases in the sequence atmospheric residue < vacuum residue < visbreaker residue < coker residue < coke.

To obtain lighter products that are richer in hydrogen, two options exist for further processing which lead to a change in molecular structure: (1) hydrogen addition ("H-in") processes (Section 3.6.3); (2) carbon rejection ("C-out") processes (Section 3.6.4).

Additional processes for particular cases are the extraction of asphaltenes and the oxidation to synthesis gas or hydrogen (see Section 3.6.5).

A combination of different process steps is often necessary because of special conditions in the plant and varying process solutions (see Section 3.6.6).

Ca. 570×10^6 t/a of throughput capacity is installed in residue conversion plants worldwide (status 1997/1998). Nearly 60 % of this capacity consist of thermal processes, the most important being delayed coking (→ Petroleum Coke) and visbreaking. The thermal processes still predominate but the proportion of hydrogenation processes (hydrorefining and hydrocracking) is increasing, particularly the processes with high conversion rates, whereas the share of catalytic cracking capacities for treating of residual oils remains relatively constant.

Table 6 shows the approximate residue conversion capacities of the various world regions

Figure 21. Residue conversion processes

(1997/1998). The resulting worldwide capacity for conversion of residual oils amounted to 14–15 % of total refinery capacity, However, the regional ratios vary widely between 4 % (Former Soviet Union, Africa, and Australia/Oceania) and 22 % (North America). In view of heavier crudes to be processed and consequently higher residue yields anticipated for the near future, a large expansion of heavy oil upgrading technologies will be necessary.

Residue conversion continues to be in a state of rapid development, thus the present review deals mainly with the problems of residue conversion and the currently best-known processes. The details of process engineering will be discussed only insofar as they differ from those of established processes. The best-known commercial processes may be summarized as follows:

Hydrorefining	Resid/HDS (Chevron)
	Resid/HDS (Gulf)
	Residfining (Exxon)
	Unicrackig (Union Oil)
	HDS (Shell)
	RCD Unibon (UOP)

3.6.3. Hydrogen Addition ("H-in") Processes

As for hydrotreating of distillates, the term *hydrotreating* is also used for the catalytic hydrogen processing of residues if the main effect is an extensive removal of sulfur and nitrogen compounds (> 90 %) as well as of heavy metals, at a relatively low conversion (5 – 35 %). *Hydrocracking* means the operation under more severe conditions with the objective of high conversion rates of ca. 60 – 90 %.

The hydrogenation processes use high pressures (5 – 20 MPa) and are expensive; the principal cost factors are the technical equipment of the plants, the expensive hydrogen supply, and the catalysts. Estimated investment costs for hydrotreating are ca. $\$ 60 - 90 \times 10^6$ per 1×10^6 t residue per year; for hydrocracking ca. $\$ 150 \times 10^6$ per 1×10^6 t residue per year.

An advantage of H-in processes – especially of hydrocracking – is the recovery of pure, high-grade products in high yields.

3.6.3.1. Residue Hydrotreating (Demetallization, Desulfurization, Denitrification)

Residue hydrotreating processes have been developed by many oil companies and by well-known engineering firms on the basis of experience in the desulfurization of gasoline and middle distillates. They are also operated predominantly in fixed-bed reactors, but with lower specific catalyst loadings (0.5 – 2 m^3 feed material per cubic meter of catalyst). So-called guard chambers are frequently installed upstream as traps for metal impurities and solids to extend the on-stream-time of the actual HDS and HDN reactors. Depending on the residue quality the on-stream times would be only up to 6 – 12 months without preliminary purification. The individual processes differ mainly in the type and number of reactors (1 – 4 in series) and in catalyst types required for the special purpose. In most cases Co-, Ni-, and Mo-containing catalysts are applied, similar to those used for distillate hydrogenation. A typical residue HDS process is shown in Figure 22.

Some processes, such as the Shell HDS process, operate with a fluidized bed ("moving bed" or "bunker flow" reactors) in order to achieve continuous catalyst exchange and avoid fairly frequent plant shutdowns.

Figure 22. Residue hydrodesulfurizer

The objective of "mild" hydrotreating processes is to obtain low-sulfur residues which can be further processed catalytically (by FCC) or used as nonpolluting fuel oils. The main market for these processes has been in Japan, where "low-sulfur fuels" are mandatory.

3.6.3.2. Residue Hydrocracking (Hydroconversion)

Despite the advantage of a high yield of clean light distillates, residue hydrocracking is used worldwide in only a few plants, because of the high plant cost and the high hydrogen consumption of 300 – 400 m^3 per cubic meter of residue.

Fluidized-bed processes are especially suitable for hydrocracking because of the prevailing severe operating conditions in combination with rapid catalyst deactivation. An additional advantage of these processes is the low pressure drop in the reactor. The catalysts used are either expensive metal catalysts, which are continuously withdrawn and regenerated, or cheap, so-called "throwaway" catalysts, which are removed from the system in a once-through operation.

Processes Using Metal Catalysts. The current commercial processes are the *H-Oil process* developed by Hydrocarbon Research and Texaco and the Lummus *LC-fining process*. In these processes ca. 0.5 – 1 kg Co – Mo or Ni – Mo catalyst are used per ton of raw material in fluidized- or ebullated-bed reactors. The two processes are very similar in technology and process outline. The fuel oil – gas mixture passes upwards through the fluidized- or ebullated-bed reactors, of which up to 4 are connected in series according to the desired cracking severity. Suspended catalyst is added at the top of each reactor to maintain the desired catalyst activity and an equivalent amount of catalyst is withdrawn at the bottom. To maintain a flow rate which holds the catalyst in suspension in the fluidized or ebullated bed and which ensures uniform (isothermal) temperature control, so-called "ebullating pumps" circulate the reactor contents from top to bottom. In the first plants of the H-Oil process these pumps were arranged outside the reactor, where they could easily be cut off and were easier accessible for repairs. In LC-fining, more effective internal pumps are used to achieve an internal recycle. A schematic representation of an LC-fining reactor is shown in Figure 23.

Figure 23. Schematic representation of an LC-fining reactor

Hydrogen is recirculated in the usual way, and the light conversion products escape rapidly overhead from the reactors, whereas the heavy material remains in the lower part so that the desired conversion can be obtained, if the residence time is sufficiently long.

Information on conversion, product yields, and degrees of desulfurization according to data from Lummus are given in Table 7 (see next page).

A modified hydroconversion process, the *Shell Hycon process*, went on stream in 1989 in a large plant with a throughput of 4000 t/d. This process involves the combination of two already proven process stages. In the first step, the metal content of the feed is reduced by 80 – 90 % with a SiO_2 catalyst in three bunker-flow

reactors. In the second step, the desulfurization and conversion is carried out in several fixed-bed reactors operated in series with a Ni – Mo catalyst on an Al_2O_3 support. The operating conditions (15 – 20 MPa and 400 °C) are similar to those for other hydrocracking processes. As the demetallization catalyst in the front-end reactors is deactivated within a short period of time, it is continuously replaced. The catalyst mass flow through the reactor is adjusted such that a shutdown cycle of ca. 2 years is obtained, which is normal for the tail-end fixed-bed reactors. The conversion is reported to be ca. 65 – 70 %, depending on residue quality. With improved catalysts at elevated temperature and with further developments in the reactor area (e.g., in material and catalyst replacement), higher conversion rates up to 90 % are possible even for extremely heavy residues [32].

Table 7. Product yields from hydrocracking at two conversion severities for an Arabian blend vacuum residue (process: LC-fining)

Product yield	Conversion, vol %	
	65	90
Gas	4.5	10.0
Gasoline	10.4	23.1
Gas oil	16.1	35.0
Vacuum gas oil	31.7	19.2
Residue	34.9	10.9
% HDS	83	89
% HDN	47	53
% Demetallization	93	96

BOC (Oil Conversion) is a fixed-bed process, licensed by UOP. The conversion is 60 – 70 % and desulfurization reaches 70 – 80 %. The reactor contains two catalyst beds separated by a specially developed "liquid – gas distributor". In the first bed the catalyst poisons and solids are removed; in the second bed the actual conversion step occurs.

Processes with Coal-Based Catalysts. A group of processes exist in which the residue is converted with pulverized coal as additive or doped with metals (preferably iron compounds) as catalyst. These processes are a further development of the coal liquefaction processes used before and during World War II, mainly in Germany. The amount of additive is between 0.5 and 5 wt %, according to the nature of the residue treated.

In *Veba-Combi-Cracking* (*VCC*), developed by Veba-Oel, liquid-phase cracking is combined with gas-phase hydrogenation of the conversion products formed. Both processes are performed at the same high-pressure level. In the first (liquid) stage (3 – 4 reactors), thermal cracking and hydrocracking reactions occur simultaneously in the fluidized bed at ca. 15 – 25 MPa and 430 – 470 °C. Oil residue, hydrogen, and catalyst are introduced at the bottom of the reactor, and a fluidized bed forms, the height of which depends on flow rate and desired conversion. The reactors have no internals and the temperature is controlled by quenching with recirculated gas. The second (gas) stage consists of a fixed-bed reactor of conventional construction with commercial HDS catalysts (Fig. 24).

The advantage of the direct combination of the two reaction stages in series is that the freshly cracked products are immediately hydrogenated before polymerization can occur to a significant extent. Furthermore, the specific energy con-

Figure 24. Schematic representation of Veba-Combi-Cracking
a) Heater; b) Liquid-phase reactor; c) Hot separator; d) Gas-phase reactor; e) Depressurizer; f) Vacuum tower

sumptions are lower because of the omission of an intermediate condensation and depressurization step followed in turn by energy-consuming pressurization.

The *Canmet process* of Petro-Canada and Partec Levalin is another process based on a coal catalyst. The process has been tested for the heavy Canadian oils and residues in several pilot and demonstration plants. Plant sizes are such as to perform up to ca. 1×10^6 t/a throughput in a single reactor. The hydrocracking reactions occur again in an up-flow reactor. A certain proportion of solid is withdrawn continuously from the bottom of the reactor. In contrast to the processes in which several reactors are connected in series, in this process the removal of sulfur- and nitrogen-containing compounds is less complete for a given conversion rate, so that larger reprocessing units are required [33].

3.6.4. Carbon Rejection ("C-out") Processes

The carbon rejection processes are designed as purely thermal or – increasingly – as catalytic processes. In these "C-out" processes, excess carbon is deposited as coke and the distillates, which still contain unsaturated hydrocarbons, must undergo further processing. Disadvantages of these coking processes include the unwanted amount of low-priced coke (→ Petroleum Coke) formed and the high gasification rate.

3.6.4.1. Thermal Processes (Visbreaking, Coking)

Visbreaking and coking (with delayed and fluid coking and Flexicoking as variants) are process types which have been known and proven in crude oil processing for many decades. The pioneering work in fluid and Flexicoking was performed by Exxon.

Because of the relatively low investment and operating costs of these processes, the oil companies are working on their further development. A particular aim is the minimization and quality improvement of the coke produced by (1) suitable pretreatment of the raw materials (optimization of the vacuum distillation, desulfurization), (2) minimization of recycle, and (3) optimization of operating parameters (pressure, temperature). *Visbreakers* are available from, e.g., Foster Wheeler, IFP, Kellogg, and Lummus Crest [34].

A typical visbreaker is shown in Figure 25. The vacuum residue feedstock is heated and cracked in a tube furnace (a) at ca. 460 – 480 °C. The furnace effluent is quenched with a cold oil stream, e.g., gas oil, which stops cracking reactions before the product enters the fractionator (b). The cracked product streams from the fractionator are routed to further treatment (e.g., gasoline hydrotreating, gas oil HDS). The visbroken residue usually has a lower viscosity and lower pour point than the feed stream.

Two-stage visbreaking is shown in Figure 26 (see next page). This process is applied for thermal cracking of atmospheric residues. The residue feed is cracked in the first stage residue furnace (a). The combined flashed distillates from the fractionator (b) and vacuum flasher (c) are subjected to a second cracking step in the distillate furnace (d). The temperature in this stage may be as high as 500 °C. This process maximizes the middle distillate (gas oil) yields, but a considerable portion of the gas oil is used as a blendstock to improve the viscosity of the cracked residue to match fuel oil specifications.

In the *coking* processes, the cracked residue is converted further to coke by allowing complete cracking within sufficient residence time [35].

Figure 27. Delayed coking
a) Fractionator; b) Furnace; c) Coke drums; d) Gas oil stripper; e) Overhead accumulator

The principle of the *delayed coking process* is shown in Fig. 27. The atmospheric residue feed is introduced to the fractionator (a) where it condenses some of the cracked vapors. The fractionator bottom product is heated in a tube furnace (b) to ca. 490 °C, and the cracked furnace effluent flows through one of the coke drums (c) in which coke is being formed and deposited. The cracked vapors from the coke drum are separated further in the fractionator. In a 24 h cycle, one of the coke drums is in use while the other is emptied by means of a hydraulic coke removal procedure.

The introduction of the *fluid coking process* brought the advantage of continuous operation, thus avoiding alternate use of the coke drums [37]. The cracking reactions occur at 500 – 550 °C in the reactor in a fluid bed of coke particles into which the residue feed is injected. Coke fines are removed from the cracked vapors in cyclone separators before fractionation. The coke formed in the reactor flows continuously to the heater, where it is heated up to 600 – 650 °C by partial combustion in a fluid bed. The heated coke particles are returned to the reactor, from where the net coke production is withdrawn.

Table 8 shows a yield comparison of delayed versus fluid coking; delayed coking has higher gasoline and coke yields, whereas fluid coking maximizes coker gas oil. Delayed coking is the preferred process for production of high-quality petroleum coke grades.

Table 8. Product yields of delayed and fluid coking

Product	Delayed coking, wt %	Fluid coking, wt %
Gases (C_4 and lighter)	7.5	6.5
Coker gasoline	17	10
Coker gas oil	53.5	72
Coke, total	22	11.5

The *Flexicoking process*, licensed by Exxon, combines fluid coking with gasification [38]. This process offers virtually full conversion of the residues to be cracked. A flow scheme is shown in Figure 28. The coke from the heater (c) of the fluid coking section is fed to the gasifier (d) and converted with steam and air to coke gas. The hot coke gas is recycled to the heater

Figure 28. Flexicoking
a) Reactor; b) Fractionator; c) Heater; d) Gasifier; e) Heat recovery – gas cooling; f) Coke fines removal; g) Cyclone separators

(c) and its heat is transferred to the fluid coke bed. The gas mixture leaving the heater is then cooled and cleaned for use as a fuel gas.

3.6.4.2. Catalytic Processes (Residue Cat Cracking)

The residue cat cracking processes represent a further development of the well-known FCC technology which has been widely used for the cracking of vacuum gas oil (see Section 3.2). The primary objective is maximum gasoline production; the $C_3 - C_4$ gases which are formed in increased yield are also converted to high-grade alkylate gasoline. For processing residues in fluid cat crackers itis essential that the contents of asphaltenes and metals, which deactivate the catalyst, are kept under a certain level. The metals content in the feed should not exceed 10 – 30 ppm, otherwise pretreatment is necessary. Since the coke deposits on the catalyst in residue crackers are considerably greater than in vacuum gas oil crackers, research efforts are being undertaken mainly to develop new catalysts (use of zeolites, regeneration techniques) and to achieve a reduction of the residence time (riser know-how). At present only feedstocks with Conradson Carbon Residue < 15 wt % can be processed which means that only 40 – 50 % of the available crudes can be used [39].

Most large-scale plants process mainly atmospheric residues with pretreatment of the feedstock. The best-known commercially operated processes are (1) Heavy Oil Cracking (HOC, Kellogg, Phillips Petroleum); (2) Reduced Crude Conversion (RCC, UOP) with regeneration in two stages; (3) Asphalt Resid Treatment (ART, Kellogg); and (4) Residual Oil Cracking (ROC, Total). In accordance with the development of the oil market, the trend in all these processes is towards conversion of heavier (vacuum) residues [40].

3.6.5. Other Processes

3.6.5.1. Extraction of Asphaltenes

Deasphalting (→ Asphalt and Bitumen, Chap. 4.2.) is a process which was developed in the 1930s for the recovery of high-viscosity lubricating oil components. In this process the residue is separated with the aid of light hydrocarbons into two fractions: a deasphalted oil (DAO) and an asphalt-rich phase. In the original process, propane was mainly used as extractant and a DAO yield of 25 – 40 wt % was obtained. The process was not operated supercritically, i.e., the solvent and extract had to be separated by evaporation and condensation of the solvent with high energy consumption. The development of the supercritical extraction process began in the 1960s with the objectives to improve energy conservation, to achieve an increased DAO yield and to simultaneously reduce the amount of residue by employing a wider range of solvents.

The deasphalting processes are characterized by low investment cost, simple technical operation, and high flexibility with regard to extract yield and quality by choice of solvent.

Interest in deasphalting processes as an alternative to residue processing is increasing because the DAO can be used as a hydrocracker

Figure 29. Schematic representation of partial oxidation
a) Reactor; b) Waste-heat boiler; c) Scrubber; d) Soot extraction

or FCC feed and because a large reduction of the unwanted residual products is achieved with DAO yields of 75 – 80 % currently feasible (see Table 9).

Table 9. Deasphalted oil yields obtained with various extractants

DAO	Feed	Extractant			
		Pentane	Butane	Isobutane	Propane
Yield, wt %		80.0	65.0	50.0	35.0
Sulfur content, wt %	5.4	4.7	4.2	3.7	3.2
Nitrogen content, wt %	0.41	0.3	0.2	0.2	0.1
Conradson Carbon Residue, wt %	25	17.0	9.7	5.5	3.1
V+Ni content, ppm	250	60	25	11	5

The extract yield which can be obtained is, however, limited by its metal content, which rises disproportionately in DAO yields of > ca. 50 %. Depending on refinery type and product requirement, the optimum must be sought between DAO yield and acceptable metal content or the costs of a demetallization stage.

Commercial plants are operated mainly in the United States and Central America for processing the heavy crude oils rich in metals and asphalt which are produced there. The best-known industrial processes are the Demex process of UOP and the ROSE (Residuum Oil Supercritical Extraction) process of Kerr – McGee.

3.6.5.2. Partial Oxidation

The partial oxidation of hydrocarbons to a mixture of $CO+H_2$ (synthesis gas) is a well-known process (→ Gas Production, Chap. 3.2.) and can be applied in residue processing within very wide limits. The noncatalytic reaction between hydrocarbons and oxygen in the presence of steam takes place at 1300 – 1500 °C in empty reactors lined with high-temperature-resistant brickwork or corundum refractory. Virtually all residues which are pumpable at the appropriate temperatures can be processed, and almost complete decomposition to $CO + H_2$ with a small (< 5 vol %) CO_2 fraction is achieved. The unburnt soot and ash fraction (≤ 5 wt %) is entrained in the synthesis gas and washed out with water in a downstream scrubber. Various possibilities exist for reprocessing this residual carbon, including complete soot recycle to the gasification reactor (Fig. 29).

The disadvantages of this universally applicable process are the relatively high oxygen costs and the production of a gas mixture of low calorific value which cannot be utilized in a standard refinery. If in the future methanol or higher alcohols become important as nonpolluting motor fuel components, the appropriate syntheses (from $CO+H_2$) could offer an interesting option. Similarly, the refineries' growing hydrogen requirement can be covered by this route even in the medium term, because pure H_2 can be produced by a simple CO-shift conversion step.

The partial oxidation process can be used in particular as a final treatment step in combination with the aforementioned processes with incomplete conversion. This also applies to the coking processes, since even the gasification of solid substances is technically possible after appropriate slurrying with oil or water.

Commercial partial oxidation processes are offered by Texaco and Shell. On a large scale, besides atmospheric and vacuum residues, also heavy thermal cracking residues (with high den-

sity and viscosity and C:H ratios of > 9.5) can be processed.

3.6.6. Process Combinations

Of the different process types of hydrogen addition and carbon rejection, which have been described in Sections 3.6.3 and 3.6.4, each has its advantages and disadvantages when used alone. A comparison of the residue conversion rates that can be achieved with the different processes is given in Figure 30.

Figure 30. Conversion rates of various residue conversion processes

The "C-out" processes of thermal and catalytic cracking are proven processes with relatively low investment and operating costs, but they give a smaller distillate yield of poorer quality and a considerable amount of unwanted byproducts.

The"H-in" processes give much higher distillate yields, but they are more expensive. Since H-in processes require catalysts, additional costs occur with increasing concentrations of catalyst poisons (reduced on-stream times, higher catalyst consumption).

Therefore, it is usually necessary to combine different conversion processing steps. A great variety of possible combinations exist with regard to conversion, amount, and quality of the desired products, as well as to the existing refinery infrastructure. They include both combinations of different residue conversion processes and further conversion units for the higher-boiling vacuum gas oils fraction, which is formed in considerable amount during the residue conversion.

The medium- and long-term trend towards the use of heavy crudes which are rich in sulfur, nitrogen, and metals, in combination with environmental problems makes it increasingly necessary to add upstream hydroprocessing stages (principally hydrotreating, and in special cases hydrocracking), followed by deeper conversion [41].

The following combined steps in the residue line are used or discussed for the planning of conversion refineries:

hydroprocessing + coking
hydroprocessing + catalytic cracking
hydroprocessing + solvent deasphalting

and as a more far-reaching step:

hydroprocessing + coking / deasphalting / hydrocracking + partial oxidation

In most cases the hydrotreater is installed in the atmospheric residue line, so that the overhead and the bottom products from the downstream vacuum tower can be fed to the subsequent conversion units in sufficiently good quality.

In delayed coking, up to now the most frequently used residue conversion process, an upstream hydrotreater results in a lower yield of coke with improved quality and increased yields of lighter products (Table 10).

Table 10. Delayed coking (feedstock: Arabian heavy vacuum residue), yield improvement by upstream hydrotreating

	Feed	
	Untreated	Pretreated
C_4, wt %	9.5	12.0
C_5 < 200 °C ∗, wt %	19.0	22.1
200 – 360 °C ∗, wt %	31.3	29.9
360 – 500 °C ∗, wt %	19.7	40.0
Coke, wt %	32.5 (fuel)	12.0 (anode)
S content, wt %	6.5	2.5
V content, ppm	300	75

∗ Boiling range of hydrocarbon fraction.

Hydrotreating of the vacuum residue alone can be considered for crudes which give a vacuum gas oil of sufficient quality to be used without pretreatment in an FCC plant or a hydrocracking process. In this case, the hydrotreater can be smaller and the yields of liquid products from the downstream coker can be increased further.

The hydrotreating – deasphalting combination likewise leads to an increased yield of liquid products, because the proportion of a DAO with reduced sulfur and metal contents, which is suitable for further processing, can be increased by up to 30 % after pretreatment of the residue in the downstream extraction step.

Partial oxidation as the possible final step in a complete residue conversion is described in Section 3.6.5.2 (Fig. 29). An important advantage of gasification is that it solves the environmental problem of sulfur, which concentrates in all residues and in coke to such an extent that these residual materials are unsuitable for combustion. In partial oxidation the sulfur compounds in the feed materials are completely converted to H_2S which can be processed to sulfur in a Claus plant.

The combinations of residue conversion processes given as examples here represent only some of the possible and useful variations. The anticipated increasing complexity of refinery processing and the more difficult technical problems to be solved, will result in a steep rise in investment and operating costs. Increasing energy prices, an increasing shortage of crude oil and its poorer quality, as well as growing environmental problems worldwide, mean that the residue problem will in the future be one of the most important tasks for crude oil processing.

3.7. Gasoline Upgrading Processes

3.7.1. Alkylation

The alkylation process is based on the reaction of isoparaffins (e.g., isobutane) with olefins (e.g., propene, butenes, pentenes) to form higher molecular mass branched paraffins in the presence of a strong acid, e.g., sulfuric acid. The alkylation product, or alkylate, is obtained as a mixture of isoparaffins with high research octane numbers, making the product an excellent blending component for motor gasolines.

A typical example of alkylation is the reaction of isobutane (1-methylpropane) with 1-butene to form isooctane (2,2,4-trimethylpentane):

Alkylation reactions are catalyzed by strong acids. The first generation of commercial units applied sulfuric acid as catalyst. During World War II alkylation plants with large capacities were installed to satisfy the drastic increase in the demand for high-octane gasoline. Alkylation units could easily be installed in refineries where olefins were readily available from catalytic cracking units. Isobutane was supplied by LPG streams, e.g., from reformers, and by C_4-isomerization. The newer generation of alkylation units used hydrogen fluoride (HF) as catalyst, which has a better regenerability than sulfuric acid.

The most commonly applied HF alkylation processes were developed by Phillips Petroleum [42] and UOP [43, 63]. A scheme of the latter process is shown in Figure 31. The olefin feed and recycle isobutane are contacted with HF in the reactor (a). The reaction product is separated in the settler (b), from where HF is recycled

Figure 31. HF alkylation
a) Reactor; b) Settler; c) Isostripper; d) Depropanizer; e) HF stripper

to the reactor, while the alkylation product is fractionated in the isostripper (c) together with mixed butane feed. The isostripper overhead product is further separated in the depropanizer (d), from where the isobutane is recycled to the feed. The propane product is freed from entrained catalyst in the HF stripper (e). *n*-Butane is drawn off as a byproduct from the isostripper. The bottom product of the isostripper is alkylate which is supplied to gasoline blending.

3.7.2. Polymerization

The polymerization process to produce additional gasoline is used mostly in refineries where excess amounts of olefins, e.g., propene and butenes from catalytic crackers, are available. The most widely applied process is the UOP polymerization, using phosphoric acid as catalyst. The C_3/C_4-olefin feed is contacted with the acid in a reactor. After separation and stabilization, the polymerate is obtained and used as a gasoline component. Another polymerization development is the IFP Selectopol process [44, 45].

The more recent IFP Dimersol process [46, 47] is a dimerization process for olefins. Three types of Dimersol processes are now available for producing gasoline components from olefins [64]:

Type G	for high-octane gasoline from propene
Type X	for octenes from butenes, or for hexenes – heptenes – octenes mixtures by co-dimerization of propene and butenes.
Type E	for gasoline from lean ethylene streams

A simplified scheme of the G-Type Dimersol version is shown in Figure 32. The feed is contacted with the liquid catalyst in the reactor. After separation from the catalyst, the reaction product is debutanized in a stabilizer column.

Figure 32. Dimersol process
a) Dimerization reactor; b) Catalyst recovery; c) Stabilizer column

3.7.3. Isomerization

Isomerization of low molecular mass *n*-paraffins has been used for a long time, particularly for isomerizing *n*-butane to isobutane in order to produce makeup feedstock for alkylation units. Isomerization gained importance after the introduction of lead-free gasolines, to compensate for the reduction in octane number. This was achieved by isomerizing C_5 and C_6 *n*-paraffin fractions to the corresponding isoparaffins and led to the development of various catalytic isomerization processes that used hydrogen and operated at moderate reaction conditions.

A typical example of this type of hydroisomerization is the Shell Hysomer process [48, 49] shown in Figure 33. The C_5/C_6-rich light gasoline feed is heated up together with hydrogen in the furnace (a) and isomerized in the reactor (b) containing a noble metal catalyst. The reaction

Figure 33. Hysomer process
a) Process heater; b) Isomerization reactor; c) Reactor product separator; d) Stabilizer column; e) Recycle gas compressor

Figure 34. Alkanolamine (DEA) gas treatment
a) Absorber column; b) Lean – fat solvent heat exchanger; c) Regenerator; d) Overhead drum

product is separated, and the stabilized isomerate run down as blending component for motor gasoline.

To maximize production of C_5/C_6 isomers, the total isomerization process (TIP) can be applied. This is a combination of the IsoSiv (Union Carbide) and the Hysomer processes, providing an iso/*n*- paraffin separation in a molecular sieve unit and subsequent isomerization of the fraction containing the *n*-paraffins.

3.8. Other Processes

3.8.1. Gas Treating

Most refinery gas and LPG streams contain poisonous and/or corrosive contaminants, e.g., H_2S, mercaptans, COS, and CO_2, which have to be removed by suitable physical or chemical methods. The gases should be moisture-free, since water in hydrocarbon mixtures may form hydrates which can plug lines and equipment.

Commonly used gas treatment processes for H_2S and other contaminants are based on chemical absorption, using regenerable solvents such as alkanolamines, e.g., monoethanolamine (MEA), diethanolamine (DEA) or diisopropanolamine (DIPA). The Sulfinol process, using a mixed sulfolane – alkanolamine solvent, is also widely applied.

As a typical example the purification of a gas stream in a DEA treater is shown in Figure 34. The gas is contacted with the "lean" (pure) solvent in countercurrent flow in an absorber column (a), where H_2S and CO_2 are absorbed by the solvent.

The "fat" (loaded) solvent enters the regenerator (c), where the contaminants are stripped off by heating and steam injection. The H_2S-concentrated gas is then routed to the sulfur recovery plant.

Caustic treatment is the preferred process for the removal of mercaptans from LPG, using alkali hydroxide solutions (e.g., caustic soda) as solvent. Dryers containing caustic soda or other desiccants are applied to remove traces of water from the LPG.

3.8.2. Sulfur Recovery

The Claus process is the most widely used sulfur recovery method for sulfur recovery, and is indispensable for most refineries with gas streams containing H_2S. The process is based on burning part of the H_2S to form SO_2, which subsequently reacts with H_2S to elemental sulfur:

$$H_2S + \frac{3}{2}\,O_2 \longrightarrow SO_2 + H_2O \tag{6}$$

$$2\,H_2S + SO_2 \rightleftarrows 3\,S + 2\,H_2O \tag{7}$$

Owing to the reaction equilibrium, the recovery of sulfur is limited to 94 – 95 %.

The Claus off-gas (containing sulfur gases) is usually burnt in an incinerator to form SO_2. The sulfur recovery can be increased to above 99.5 % by applying a separate treatment process, e.g., the Shell Claus Off-gas Treating (SCOT), in which the SO_2 is catalytically converted to H_2S, and the H_2S is absorbed by means of solvent (DEA) circulation to and from the Claus unit.

4. Environmental Protection in Oil Refining

4.1. Introduction [50–52]

The natural product crude oil and the products obtained from it are generally easy to handle and with careful treatment – which is necessary because of their flammability – they cause little pollution to the environment. (The CO_2 emissions associated with all fossil fuels and the corresponding effects on the earth's climate cannot be considered in this context.)

Figure 35. Petroleum's route from the well to the consumer shown as an example for Germany

Environmental problems arise, however, in dealing with crude oil and its products because the petroleum industry – like hardly any other branch of industry – maintains exploration, transport, and refining installations for crude oil that are scattered over the entire globe. The distribution and consumption of burning and transportation fuels are even more scattered (Fig. 35). Since the geographical location of crude oil fields does not coincide with that of the large consuming and refining regions, enormous transportation distances exist. The large amounts handled – the annual refining capacity in 1988 was ca. 3×10^9 t in more than 600 refineries worldwide – means that the industry needs to take precautions in all areas with regard to air emissions, water and soil pollution and, to a lesser degree, noise. The problems of introducing uniform standards are caused by legal standards which differ from country to country depending on the local concentrations of industrial areas with their corresponding environmental pollution and population density.

Because of the high cost of technical measures for environmental conservation, harmonization of legislation is absolutely necessary. As these costs amount to more than 25 % of the total processing costs in the refineries equal competition between different countries must be guaranteed (see Section 4.4).

In the following chapters, the environmental problems in crude oil refining, storage and loading, and in the application of the products are discussed separately, because the problems in the various fields differ.

4.2. Manufacturing Emissions

Although closed, gas-tight systems are generally used in refinery units, emissions into air and water cannot be completely avoided even with careful handling during refining and storage of the crude oil and its products. This is due to the management and control of the process and the properties of the products concerned.

Hydrocarbons are discharged into the air because of their high vapor pressure and they appear in refinery wastewater effluents because of their water solubility, which is, however, small. The carcinogenic aromatic hydrocarbons are particularly dangerous.

Further attention must be paid to the sulfur and nitrogen compounds originating from the heteroatomic compounds in the crude oil, both because of their smell and toxicity and because of the air pollution which arises in the form of

SO_2 and NO_x emissions during firing in process plants.

4.2.1. Hydrocarbons (HC) [53]

4.2.1.1. Hydrocarbons in Air

Hydrocarbon emissions can arise in *production plants* during normal operation (1) from leaking flanges in the pipework system; (2) at the seals of valves, pumps, and compressors; and (3) in the course of sampling. In the case of an accident, gases are led in closed systems to flares, collected as far as possible in gas recovery systems, compressed and returned to the process. The remainder of the gases is burnt in elevated or ground flares at efficiencies which can exceed 99 %. Liquid products are collected in closed slop systems that are equipped with pressure reservoirs and tanks and later returned to the production circuit.

In new plants measures to reduce emissions are taken during their construction, whereas continuous retrofitting is necessary in existing plants. Examples are flangeless piping, low-emission stuffing boxes, and seals, such as duplicated slide ring packings. For intensely odorous, poisonous, and carcinogenic substances more far-reaching measures are necessary (canned-motor pumps, special extraction devices etc.).

Most hydrocarbon emissions in processing occur in the *storage areas*, i.e., tank farms for crude, feedstocks, intermediate, and final products. Pressure – vacuum relief valves and floating cover tanks are generally used to reduce emissions. More recent developments are emission-free tank farms, where several fixed roof tanks fitted with internal floating roofs breathe into a closed system at one common gasometer, which normally absorbs all changes in the tank level. In the rare event of unusually large changes in the system (large amounts flowing into or out of storage, solar irradiation, heavy rain), the surplus quantity is burnt harmlessly in an associated flare or, in the case of a pressure drop, the system is topped up with inert gas.

Considerable amounts of hydrocarbons are also emitted in the *loading facilities*, especially in the loading of gasolines. Here low-emission or emission-free loading for transport by ship, rail, and road has become largely accepted. Various methods are used (Fig. 36):

1) Vapor recovery, where in a closed system the displaced gasoline vapors are either returned to the product tank or collected in a gasometer and used for the firing of process plants
2) Regenerative adsorption of the vapors on suitable adsorbents
3) Recovery of the products in liquid form after cooling or washing out the vapors

Care must be taken to prevent the formation of explosive gasoline – air mixtures which can occur in the road tanker to be loaded and in the adjacent piping and equipment.

This can be achieved by (1) keeping the concentrations outside the explosive range, (2) short transportation paths and exclusion of ignition sources, and (3) extremely strict control of the oxygen contents.

Dispensing of gasoline from the road tanker to the service station is also increasingly carried out with vapor recovery between the road tanker

Figure 36. Emission-free loading and unloading of gasoline hydrocarbons with off-gas purification (refinery, intermediate storage)
a) Storage tank with floating roof; b) Exhaust gas washes (gasoline); c) Fine purification (adsorption); d) Low-temperature cooling (to − 40 °C)

and the installed storage tank of the service station. The possibilities of reducing emissions in the final step (filling the customer's motor vehicle) are described in Section 4.3.1.

The measures described reduced the atmospheric emissions from processing, storage, and distribution of refinery products in the mid 1980s in Western Europe to $< 8\,\%$ of the total man-made HC emissions. The portion from the refineries themselves was in turn only a quarter of this value. More recent investigations by CONCAWE show further improvements. Thus, relative to the crude oil throughput, refinery emission losses of ca. 0.05 wt % are expected, depending on the structure and size of the plant. For inland refineries in Germany, for example, values of 0.02 – 0.03 wt % have been published.

4.2.1.2. Hydrocarbons in Wastewater

Hydrocarbon-containing wastewater is unavoidably obtained at various points in the refinery because of the water content of the crude oil itself and because steam is employed in various processing steps. The total amount of hydrocarbon-containing wastewater in a normal refinery is of the order of 60 – 100 m^3/h.

This wastewater must be removed from the process units after separation of the oil phase, and led via a closed system to wastewater purification. Rainwater from exposed plant areas and from tank yards, and possibly contaminated cooling water from leaks or accidents must be treated in the same way. Considerable buffer volumes must be made available for the latter amounts of water which are formed discontinuously and sometimes in large quantities.

Treatment in the wastewater purification system is carried out stepwise by:

1) mechanical separation (sieves, filters, oil – water separators)
2) physicochemical purification (stripping, flocculation, flotation)
3) biological treatment

Biological wastewater treatment of hydrocarbons in refinery wastewaters is normally problem-free. However, the incoming streams and corresponding buffer volume must be continuously monitored to detect pollution by sulfur or nitrogen compounds and by oxygen-containing components such as phenols.

In many countries there is an increasing legal requirement for covered water treatment plants to avoid odor and for total nitrogen removal for further protection of surface waters (rivers, lakes etc.). The latter usually requires an additional purification stage with increased residence time.

After the biological stage, the water is clean and can be discharged into the receiving water. The average analyses of the wastewater from a modern refinery (in mg/L) are:

COD	60 – 100
BOD	5 – 15
Oil	0.5 – 2
Settleable solids	0.1 – 0.3
Phenols	0.1 – 0.2

As a result of increased wastewater purification, the amount of hydrocarbons discharged by the refineries in Western Europe was reduced by ca. 90 % in the period 1970 – 1985 for about the same amount of crude oil processed (Fig. 37) [54].

Figure 37. Development of the discharge of hydrocarbons with wastewater in Western Europe (reports from 87 refineries, ca. 80 %)

4.2.1.3. Hydrocarbons in Soil and Groundwater

Since hydrocarbons are water-soluble (even if only to a small degree), their penetration into the soil with possible contamination of the groundwater must be carefully avoided, whenever crude oil or any of its products are handled.

Transport from the oil terminal to the refinery is carried out almost exclusively in underground pipelines, which are also the safest means of

transport. The choice of high-grade steels as construction material, good insulation, cathodic corrosion protection, and continuous monitoring for leaks, including visual monitoring from aircraft or ground inspection, ensure a high level of safety. On difficult terrain and in areas of extreme temperature fluctuations, additional measures must be taken (pipeline compensation, elevated piles, intermediate tanks etc.).

The location of the refinery must be carefully selected with regard to possible dangers to drinking water. According to new legislation, all HC-handling units must be erected so as to prevent the discharge of spilled product to the underground, to adjacent streets, or canals; the storage tanks are placed in collection spaces which are made impermeable to oil using clay layers, plastic tilts, or concrete lining; in case of a leak they must be capable of receiving the entire tank contents.

If hydrocarbon contamination occurs in the soil, the affected portion of soil must be removed to prevent subsequent pollution of groundwater. If small amounts have escaped, the contaminated soil is usually combusted in incinerating plants. With larger amounts – and particularly if large areas are polluted with chemical residues and dangerous refuse – the damage must be treated in situ. Depending on the nature of the soil and the corresponding migration of the oil, this can be done by pumping off and purifying the contaminated water, possibly by additional injection of fresh water in adjacent wells.

Degradation of the oil by microorganisms is becoming increasingly important. This can also be done in situ or by excavating the soil and treating it externally [55].

Loading and storage of the products outside the refinery are subject to similar regulations. However, these are still very different in individual countries. As a result of the large number of external distribution depots for transport fuels and heating oils and of service stations, and because of the enormous number of oil-heated households, special care must be taken against overfilling and escape of products due to leaks. Corrosion-resistant and nonageing steels, plastic-lined steel tanks, and novel, glass-fiber-reinforced, plastic tanks are widely used. These tanks must also be constructed such that the whole volume can be collected if leakage occurs (doublewalled tanks).

In some countries with a population density and dense housing and industrial areas, the regulations which apply to pure hydrocarbons (i.e., products) are also applied to the handling of process water with much lower HC-concentrations.

4.2.2. Sulfur and Nitrogen Compounds

As a natural product, crude oil also contains heteroatomic compounds containing sulfur, nitrogen, and oxygen in addition to hydrocarbons. Whereas the nitrogen and oxygen contents are in the ppm range and play only a secondary role in atmospheric emissions, the sulfur content of the crudes can be as high as several percent. The distribution over the individual refinery fractions varies, but the content increases with increasing molecular size.

4.2.2.1. Sulfur Compounds

Sulfur and its compounds are catalyst poisons and adversely affect atmospheric emissions. Hydrogen sulfide, mercaptans, and disulfides are odor nuisances, and sulfur dioxide is formed during the combustion of crude oil products. Therefore, sulfur and its compounds must be removed or their contents reduced.

The light refinery products, liquefied petroleum gas (→ Liquefied Petroleum Gas, Chap. 2.) and gasoline, must be almost completely sulfur-free (→ Automotive Fuels, Chap. 8.); for diesel fuels (→ Automotive Fuels) and light heating oils (→ Heating Oil), a substantial sulfur reduction to 0.1 – 0.5 % is required by recent legislation.

Serious problems exist with heavy fuel oil (→ Heating Oil, Chap. 1.7., → Heating Oil), which is used almost exclusively as fuel in large industrial furnaces and power stations and leads to considerable SO_2 emissions. Many countries have established a maximum sulfur content in fuels of 1 – 2 wt %. This value can be reached without additional treatment only with a few, low-sulfur crude oils, whose supplies are limited (→ Heating Oil).

Sulfur is generally removed from distillates by hydrodesulfurization, whereby the chemically bound sulfur is converted to hydrogen sulfide. The H_2S is then removed in a gas scrubber,

converted to elemental sulfur in the downstream Claus process, and supplied to the chemical industry as a raw material.

The intense smell of the H_2S-containing gases to be processed and the high toxicity of H_2S, even at high dilution, means that precautions must be taken when handling. All sulfur-processing plants must be completely gastight: in the hazard zones, instruments and alarm devices are installed which automatically shut down the plants in case of danger.

Sulfur recovery in refineries has increased greatly as the result of the lower permitted sulfur content of the products. In conventional Claus plants with two reactors connected in series the conversion of the H_2S feed is ca. 95 %, a third reactor increases the conversion to 96 %. For a further reduction of the H_2S content an aftertreatment step (Scot process, Sulfren, see → Natural Gas) is required. Almost complete removal that is required in various countries (e.g., Germany 10 ppm H_2S in off-gas) can only be achieved with an additional high-temperature combustion step. Figure 38 compares the sulfur removal from the processed crude oil with the crude oil capacity in West German refineries for the period 1970 – 1988. The increase in sulfur removal resulted in a dramatic reduction of overall SO_2 emissions since most of the desulfurized hydrocarbons are used as fuels.

Figure 38. Sulfur removal during crude oil processing

Sulfur dioxide emissions in the refineries themselves are relatively small. Depending on the refinery complexity, only 4 – 6 % of the crude oil used is required for fueling in the process plants. About half of this amount is covered by the low-sulfur or sulfur-free gases obtained during processing, and the remainder is heavy fuel oil. With more severe requirements to lower SO_2 emissions, the refiner might be forced to use as fuel all of the LPG that is produced in the refinery.

Legislation differs greatly in the individual countries: the stipulated limitvalues can be related to a single process unit, a stack, or the refinery as a whole and can refer to the total sulfur discharged or the sulfur concentration in the flue gas. Combinations of several measures are also possible, and so-called "bubble concepts" are used, particularly in the United States. (Bubble concept means that for a given amount of emission from the total complex, different limit values or amounts discharged are allowed for each individual plant.)

The expensive flue gas desulfurization is normally uneconomic for firing installations of the size of those employed in a normal refinery. Therefore it is used only in special cases, e.g., if the refinery is connected with a large power station or if the sulfur content of the fuel is extremely high.

4.2.2.2. Nitrogen Compounds

The nitrogen content of most crude oils is relatively low, and in the distillates it is reduced during hydroprocessing to a few ppm. The residual nitrogen content causes no further difficulty in the use of the products.

Ammonia, which is formed in the hydrogenation steps and added in many refineries for process control in various process stages (pH adjustment), enters the wastewater and can be removed in the biological stage of wastewater purification (see Section 4.2.1.2).

For the NO_x problems in connection with the combustion of fuel oils, see → Heating Oils, Chap. 2.6.

4.2.3. Noise

In the past, noise pollution in the neighborhood of petroleum refineries played only a secondary role. Worldwide, pumps and compressors were installed not in closed buildings but in the open air, because of the flammability of petroleum

and its products. However, because the plants were smaller at that time, the noise emission of the units was relatively small. In addition, the sound radiation from furnaces and their burners produced relatively low sound levels in the refinery surroundings, because of the compact construction of the main process plants that were simultaneously screened by lownoise auxiliary installations (tank farms) at the periphery.

Problems arose, though, in densely populated areas with insufficient distances between industrial and residential areas. Most noise problems were caused by flare noise in the event of process disturbances.

Owing to growing environmental awareness in the public and a correspondingly greater strictness of legislation, further measures will have to be taken in the future to reduce sound emissions. This is also necessary for technical reasons, because the complex conversion refinery maintains more and larger units with greater furnaces and higher-powered gas compressors with high-speed steam turbines etc.

Important measures for noise reduction could cover the following items:

1) Low-noise burners and additional noise insulation on process heaters and piping.
2) Sound hoods on the drive motors and turbines of pumps and compressors. A complete "in-housing," however, may also give rise to safety problems, because fire fighting is more difficult and the danger of explosion is greater in closed rooms.
3) Sound insulation on control valves.
4) Low-noise flare stack tips for elevated flares or additional ground flares.

A noise reduction by 10 dB(A), i.e., a reduction of the observable noise level by about one-half, is possible according to the states of the art, though only with considerable expenditure.

4.3. Consumer Related Emissions

The emissions of SO_2 and NO_x from the combustion of refinery products outside the refinery are much greater than the emissions during refining itself. In addition, the HC emissions in the transportation field, both in refueling and in running motor vehicles, are also considerably greater than in the steps from production to the filling station (see Table 11).

Table 11. Hydrocarbon emissions in the petroleum field (Western Europe 1986)

Source of emission	Proportion	
	10^3 t	%
Crude oil production	20	0.4
Refinery, storage	170	4.1
Distribution	310	7.4
Vehicles		
Refueling	180	4.3
Exhaust gas	2500	59.7
Evaporation	1010	24.1
Total	4190	100.0

4.3.1. Transportation Fuels

When gasoline is combusted in the spark ignition (Otto) engine, varying amounts of CO, NO_x, unburnt hydrocarbons, and lead compounds are emitted with the exhaust gas in addition to the combustion products water and CO_2. The amounts differ according to the driving style, type of fuel, and engine construction. With the diesel engine, SO_2 and soot particles are also emitted, → Automotive Fuels, Chap. 3.2.9.

In addition to exhaust emissions, the emission of hydrocarbon vapor during refueling and running of motor vehicles is an important environmental pollution factor.

4.3.1.1. Motor Gasoline [56]

Different factors cause emissions of hydrocarbons from motor vehicles: firstly, the unburnt hydrocarbons in the motor vehicle exhaust, and secondly, the hydrocarbons emitted during refueling and running, because of their high vapor pressure. In Western Europe in 1986, the emissions (in 10^3 t/a) were distributed as follows:

Exhaust emissions	$2500 \triangleq 68\,\%$
Evaporative emissions	$1010 \triangleq 27\,\%$
Refueling losses	$180 \triangleq 5\,\%$

Specific measures are provided to reduce these different types of emission either in the motor vehicle or at the filling station.

For exhaust emissions, the use of catalysts in the exhaust gas line has generally become accepted (→ Automobile Exhaust Control).

Figure 39. Reduction of hydrocarbon emissions
A) Vapor recovery at the service station; B) Large carbon filter in the motor vehicle
a) Gas displacement pipe; b) Vent; c) Gas venting valve actuated by filling nozzle; d) Gas – liquid separator; e) Gas line; f) Magnetic valve and regeneration control orifice; g) Standard gas vent and overturn protection; h) Outlet; i) Fuel tank; j) Liquid seal in filling tube (reduces escape of gases); k) Activated carbon filter with 4.5 L capacity (traps gases)

Efforts to reduce evaporative emissions and refueling losses are less clear-cut. Their proportion in the emissions from the motor vehicle sector is ca. one-third of the total output, corresponding to ca. 12 % of the total man-made emissions of organic substances.

Two solutions are under discussion (Fig. 39) [57]:

1) Vapor recovery at the service station, possibly supplemented by a smaller activated carbon canister in the motor vehicle.
2) A larger activated carbon canister fitted into the car, whose charge can adsorb all of the displaced hydrocarbons.

Vapor recovery at the service station is only a partial solution, because most of the emission is produced when the car is running and is not influenced by this measure. The advantage of vapor recovery is that it can be carried out at the service station within a rather short period of time. The system is already in use in the United States. The large activated carbon canister ("on-board system") is considered to be the better solution in the long term because of its greater effectiveness and lower cost. Technical trials have been carried out with various types of vehicles. Installation in new cars presents no problems; retrofitting to old vehicles will, however, only be possible in a few cases.

Owing to the wide use of motor fuels, particular attention must be paid to benzene emissions. The limit for the benzene content of gasoline (1 – 5 vol % is under discussion) presents the oil industry with problems, particularly in the production of unleaded gasoline, because the benzene content of various blending stocks can be considerably higher, depending on the quality or origin of the crude, up to 8 vol % for high severity reformate and 18 – 40 vol % for pyrolysis gasoline. Benzene extraction from HC-stocks does not solve this problem because of the cost and the question of reuse of the benzene recovered. Therefore, the evaporative losses must be minimized.

4.3.1.2. Diesel Fuel

The main exhaust gas problems of diesel vehicles concern the emissions of soot particles and SO_2. The NO_x and CO components are less important than in the spark ignition (Otto) engine. Demands are increasingly being made for a reduction of these emissions, because of the smell of the exhaust gases, and because the soot particles may have a carcinogenic effect. Emission reduction of diesel fuels is discussed in more detail in → Automotive Fuels, Chap. 3.2.9.

4.3.2. Burning Fuels

The largest proportion of refinery products worldwide is used as a fuel for domestic or industrial heating as well as for energy production. These are the fractions of LPG (→ Liquefied Petroleum Gas) the middle distillates, and heavy fuel oil (→ Heating Oil). Emissions of SO_2, NO_x, and CO that are associated with combustion, as well as emission of ash and unburnt carbon (in the form of soot) can be considerably influenced by selection and pretreatment of the products used and by the burner design. This is particularly true for the large heating installations operated with sulfur-rich heavy fuel oils.

Liquefied Petroleum Gas (→ Liquefied Petroleum Gas). The liquefied petroleum gases used as fuels are almost sulfur-free as a result of pretreatment in the refineries, and they burn without formation of soot. Their use presents no problem for the user.

Light Heating Oil (No. 2 Fuel) (→ Heating Oil, Chap. 1.). Middle distillates contain up to 1.5 wt % sulfur, depending on the origin of the crude. Most of the sulfur can be removed in the refinery by hydrosulfurization (see Section 4.2.2).

The permissible sulfur limits for light heating oil in most countries are < 0.5 wt %, because of its use in domestic heating. In the EU, the sulfur content of domestic heating oil is now limited to 0.2 wt % (→ Heating Oil, Chap. 1.7.). If lower sulfur contents are to be achieved, desulfurization costs will rise steeply with the current range of crudes, according to studies by Concawe [50] (Fig. 40).

Figure 40. Investment to reduce gas oil sulfur in Western Europe

Heavy Fuel Oil (No. 6 Fuel). The residues from crude oil refining are used as heavy fuel oil for industrial heating and energy production. Sulfur dioxide, nitrogen oxides, CO, and particulate emissions must be considered for heavy fuel oils; for environmental protection measures in this field, see → Heating Oil, Chap. 2.

4.4. Cost of Environmental Conservation

Because the understanding of environmental problems, technical solutions, and legislation are still in rapid development, a view of the expenditure on environmental conservation can only be predicted. This estimation is necessary for an overall view of the problem, because the costs of environmental conservation have reached such a high level that they markedly influence the total processing costs. The great variety of possible solutions worldwide and the different legislation in the various countries and regions also have a corresponding impact on costs.

Besides the investment costs required for new plants (15 – 20 % of the total cost is used for environmental conservation) and the conversion of old plants, there are continuous operating costs

for energy, maintenance, personnel, etc. It is difficult to give current, generally applicable figures due to the increasing debate on the environment and the rapid development in this sector. Table 12 shows the growth of environmental conservation costs in Germany from 1977–1987.

Table 12. Investment and operating costs for environmental conservation in the Federal Republic of Germany in comparison with crude oil processing

	1977	1979	1981	1983	1985	1987
Crude oil processed, 10^6 t/a	99.5	109.6	98.9	90.2	87.3	81.4
Investment costs, 10^6 DM	294	127	130	305	103	221
Operating costs, 10^6 DM	826	894	1129	1212	1097	900

A study was set up in 1986 by the Commission of the European Communities to determine the environmental conservation costs for refineries in the EC member countries [59]. This considered the current (1985) and future (1993) operation of typical refineries and determined the costs of keeping to environmental regulations – at the refinery sites and with regard to product specifications. The current standards and regulations and those expected in future were taken into account. The most important measures in the processing field are:

1) Gas washing systems and Claus plants for sulfur recovery from H_2S followed by fine purification.
2) Closed systems for the discharge of gaseous (via a flare) and liquid hydrocarbons.
3) Floating roofs and floating covers in storage tanks for crude oil and products.
4) Hydrocarbon vapor recovery systems for the storage and loading of volatile products.
5) Collection spaces for escaping hydrocarbons and precipitation water in production plants, tank farms and loading plants. Drainage to wastewater purification plants.
6) Reduction of emissions (SO_2, NO_x) from the plant's firing installations.
7) Closed sampling systems, laboratory analysis, and on-line instruments for pollutant measurement in air and wastewater.

The following measures are for the production of less polluting products:

1) Hydrodesulfurization of gasoline and middle distillates.
2) Reforming and isomerization for the production of high-octane components as a basis for unleaded gasoline.
3) Synthesis of suitable components for unleaded gasoline (MTBE).
4) Conversion of heavy residues into light, clean products.
5) Separate storage and loading of unleaded types of transportation fuels.

In determining the measures required and the resulting costs, the study considered the environmental conservation laws applicable in each EC member country at the time concerned or scheduled up to 1993. The results are given in Table 13.

Table 13. Environmental costs of petroleum processing in the EC member states (in ECU/t)

Country	1985	1993 EC directives only	1993 EC+national regulations
Belgium	1.01	6.25	8.57
France	1.05	3.11	4.54
Germany	3.38	5.87	19.28
Italy	0.34	2.15	2.52
Netherlands	1.01	6.12	17.07
Spain	0.31	3.21	3.58
United Kingdom	0.28	6.64	7.01

They show that: (1) the environmental costs rose in all EC countries; (2) there are large differences in cost between the individual countries; (3) for comparable costs arising from the EC directives, the additional national legislations lead to different costs; (4) the burden of environmental costs is in some countries of the same order of magnitude as that of the other processing costs.

The figures given are more likely to be near the lower limit: the study did not, e.g., consider noise protection measures, soil clean-up or special regional regulations, because these can differ greatly according to the location of the refinery. Moreover, the conservation of groundwater and consideration of climatic changes are becoming increasingly important, and are continually leading to a tightening of the limits of the (current) standards.

The investigations carried out for the EC can be applied to all other regions of the world. Taking into account the high expenditure for minimizing potential dangers (flammability, explo-

sion risk, transport risks) and for protection of the plant workers, crude oil refining is burdened with extremely high additional costs related to product value and technical efforts.

5. Integrated Refinery Models

5.1. Trends of Refinery Structures

The drastic increase in crude oil prices in 1973 – 1974 and 1979 – 1980 as well as changes in the product demand pattern in major consumer regions, i.e., North America, Europe, and Japan, have led to new considerations in integrated refinery processing to achieve better utilization of residual materials, a maximization of distillate production, an improvement in process economics, and to meet current environmental standards.

These trends resulted in a worldwide restructuring of oil refining with the aim of increasing the yields of the high-value products – chiefly transportation fuels and industrial feedstocks – at the expense of low-value heavy fuel oils. Great efforts were made to change from the simple "hydroskimming" type refining scheme to more complex refinery structures with integrated residue conversion processes. A comparison of three conversion concepts versus hydroskimming is given by the following schemes which are based on Arabian light crude processing [60]. Examples of developments in thermal and catalytic cracking processes for heavy fuel oils and of developments in residue hydroprocessing, both in integrated refinery structures, are given in [61] and [62], respectively.

5.2. Hydroskimming Refinery

The process configuration, known as hydroskimming or "fuel oil refinery," is shown in Figure 41. The plant lineup consists of a crude distillation unit, hydrotreaters for gasoline and gas oil, a catalytic reformer, and a gas and sulfur workup section. It does not include a residue conversion unit. Atmospheric residue with a yield of 43.5 % of the crude represents by far the largest product portion, which has to be marketed as heavy fuel oil.

Figure 41. Hydroskimming

Table 14. Yield structures of refinery conversion schemes for Arabian light crude processing [60]

Product	Hydroskimming [a]	FCC – VB [b]	HC – SDA – FCC [c]	HC – Coking [d]
Intake, wt %				
Crude oil	100.0	100.0	100.0	100.0
Hydrogen			0.4	0.5
Output, wt %				
Fuel gas	1.8	3.4	3.1	4.7
LPG	1.6	3.0	2.9	2.9
Chemical feed	2.0			1.7
Gasoline	15.9	33.0	32.9	24.4
Kerosene	9.6	9.6	9.6	9.6
Gas oil	25.3	26.3	40.2	50.9
Fuel oil	43.5	22.7	9.2	
Coke		1.0 [e]	1.1 [e]	5.0 [f]
Sulfur	0.3	1.0	1.4	1.3

[a] Hydroskimming = refinery configuration without residue conversion processes.
[b] FCC – VB = conversion scheme with cat cracker and visbreaker.
[c] HC – SDA – FCC = conversion scheme with hydrocracker, solvent deasphalting, and cat cracker.
[d] HC – coking = conversion scheme with hydrocracker and coker.
[e] Coke burnt in FCC unit.
[f] Coke produced in coker unit.

The naphtha yield is 17.9 % of the crude (15.9 % gasoline and 2 % chemical feedstock), and the middle distillates amount to 34.9 % (9.6 % kerosene, 25.3 % gas oil). A comparison of the product yields of the hydroskimming refinery with the yield structures attainable with different conversion concepts is given in Table 14.

5.3. Conversion Concepts

5.3.1. Cat Cracking – Visbreaking Refinery

A typical refinery for maximum gasoline production using an FCC unit is shown in Figure 42. The FCC feedstock, vacuum gas oil, is produced by vacuum distillation and pretreated in a hydrodesulfurizer for sulfur removal and FCC yield optimization. In a visbreaker unit, the vacuum residue is thermally cracked to produce additional distillates. As can be seen from Table 14, the residue output from this refinery type is 22.7 % of the crude, i.e., only about half of that of the hydroskimming type. The gasoline yield amounts to 33 % and middle distillates make up 35.9 % of the crude.

Figure 42. Catalytic cracking – visbreaking

5.3.2. Hydrocracking – Cat Cracking Refinery

A high-conversion refinery which combines fluid catalytic cracking and hydrocracking is shown in Figure 43. The HC feed is vacuum gas oil, whereas the FCC feed (deasphalted oil) is produced in a solvent deasphalting unit and desulfurized in a HDS unit. The asphalt product of the SDA unit can be used as heavy fuel oil; however, it must be blended with a "fuel thinner" (middle distillate) to meet fuel specifications. The hydrogen produced in the catalytic reformer is not sufficient for supplying the HC unit, therefore makeup hydrogen is produced in a steam reformer. As shown in Table 14, the net fuel oil portion is only 9.2 % of the crude. Gasoline and middle distillate yields are 32.9 % and 49.8 % respectively, i.e., an improvement in comparison with the two schemes previously described.

5.3.3. Hydrocracking – Coking Refinery

The hydrocracking – coking refinery is illustrated in Figure 44. In this configuration the production of middle distillates is maximized by using a hydrocracker and a coker. Vacuum residue is used as coker feed while the HC feed is a combination of vacuum gas oils and heavy coker distillates. As in the previous scheme, extra hydrogen has to be supplied from a steam reformer.

The only residual product is 5 % coke (Table 14) which can be sold to the chemical industry or for electrode manufacturing (→ Petroleum Coke). Since no heavy fuel oil is produced, this process configuration is often referred to as a "zero-fuel" refinery. The yield of middle distillates (kerosene and gas oil) is > 60 % and the naphtha yield (gasoline and chemical feedstock) is 26 %.

6. Corrosion and Materials

Prevention of corrosion in refining equipment is determined by material selection in plant construction and day-to-day operational control. As various corrosion criteria are dealt with elsewhere (→ Corrosion), only the main refining-related corrosion problems and the selection of corrosion-resistant materials are summarized as follows:

Corrosion problems are mainly caused by organic sulfur compounds and inorganic chlorides in crude oils. The danger of steel embrittlement by hydrogen in all processes involving hydrogen must also be taken into account.

Corrosion in distillation processes is caused by the following:

1) Formation of iron sulfide and subsequent corrosion by H_2S and mercaptans at elevated temperatures. Suitable materials for corrosion prevention are Cr and austenitic Cr – Ni alloys, particularly for transfer lines and reboiler tubes, and Cr – Mo alloys for furnace tubes. The lower parts of the crude and vacuum columns should be lined with Cr steels.
2) Attack by naphthenic acid to form iron naphthenates and subsequent corrosion. Austenitic Cr – Ni – Mo alloys can be used and naphthenic acid can be removed upstream of the columns.
3) Hydrogen chloride corrosion in overhead condensation systems. Monel or other Ni – Cu alloys can be used. Measures which can be taken to prevent corrosion include desalting of crude oils, neutralization of overhead vapors with ammonia, and pH-control, and use of corrosion inhibitors in endangered equipment sections.

Corrosion in cracking processes is caused by the following:

1) *High-Temperature Sulfur Corrosion.* Cr – Mo alloys in the furnace and heat-exchanger tubes and Cr steel lining in the columns are suitable materials for corrosion prevention.
2) *Erosion by Catalysts.* Ceramic and concrete linings in vessels and cyclones and regenerator internals made of Cr – Mo and austenitic Cr – Ni alloys are suitable materials.

Corrosion in hydrogen-carrying processes is caused by hydrogen attack at high temperatures (blistering and embrittlement of steels). Cr or Mo steels, at higher temperatures austenitic Cr – Ni alloys, can be used to prevent corrosion. In the presence of hydrogen and H_2S, i.e., in hydrotreating and hydrocracking processes, steels with high chrome contents must be used.

Figure 43. Hydrocracking – catalytic cracking

Figure 44. Hydrocracking – coking

7. Testing and Analysis

The chemical and physical properties of crude oils and their fractions depend on the types and concentrations of their consituents. The typical properties of crude oils and their products must be defined and determined by analytical methods, to meet quality requirements for production, transport, storage and handling of crude oils, and to assess specific quality criteria for further processing of products.

This quality testing is performed by regular laboratory analysis or by automatic instruments.

7.1. Crude Oil and Product Properties

Density and API Gravity. The density ranges of various crudes are as follows:

Paraffin-based crudes	815 – 835 kg/m^3
Mixed-based crudes	835 – 860 kg/m^3
Naphthalene-based crudes	860 – 955 kg/m^3

The API gravity (introduced by the American Petroleum Institute) is the internationally used density measure for crude oils. The relation between degrees API and density at 15 °C is:

$$^{\circ}\mathrm{API} = \frac{141.5}{\mathrm{Density\ [kg/L]}} - 131.5$$

Distillation. The *boiling range* of crude oils is one of the most important quality criteria for determining the yield distribution of the different product fractions. Boiling analyses under atmospheric conditions can be supplemented by distillation under reduced pressure for oil fractions that boil above 360 °C.

More detailed and precise results are obtained by applying fractional or *true boiling point* (TBP) distillation.

Viscosity. The viscosity of crude oils is determined by the ratio of low and high molecular mass constituents in the oil. The kinematic viscosity of crude oils (at 38 °C = 100 °F) can vary from 4 mm^2/s (0.04 St) for light (North Sea) crudes to 700 mm^2/s (7 St) for heavy (Venezuelan) crudes.

Flash point. The flash point depends on the concentration of light (low-boiling) constituents. For crude oils, flash points between − 20 °C and + 80 °C are observed.

Pour Point. The pour point is the temperature at which an oil or oil product ceases to flow. It is an important measure of its cold flow properties. (→ Automotive Fuels, Chap. 5.2.3.).

Other properties that are analytically tested include specific heat; calorific value; contents of sulfur, nitrogen, oxygen, and inorganic compounds; the C/H ratio; the hydrocarbon composition; and product-specific criteria (see Section 2.3).

7.2. Testing Methods and Standards

In the oil industry a framework of standard analytical procedures has been established, e.g., by ASTM, DIN and the British Institute of Petroleum, (IP) standards. In addition, various house standards have been introduced by most international oil companies.

A selection of frequently applied DIN methods is listed below:

Density	DIN 51757
Distillation (boiling range)	DIN 51751
Vacuum distillation	DIN 51356
Fractional distillation	DIN 51567
Flash point	DIN 51755, 51758, 51376, 51584, 53213
Viscosity	DIN 53012, 51550
Cold properties (cloud point, pour point, freezing point)	DIN 51583, 51597, 51421
Water content	DIN 51582
Water and sediment content	DIN 51793
Salt content	DIN 51576
Sulfur content	DIN 51400, 51768, 51409, 51418, 51450

Analytical testing by *automatic continous analyzers* has come into use worldwide. The continuous analysis of process streams by automatic "onstream analyzers" has proven to be an indispensable tool for the quality control of products in integrated refining systems.

8. Storage and Transport

Surface Storage. *Crude oils* are stored in cylindrical fixed-roof or floating roof tanks; *LPG* is stored in spherical or cylindrical pressure vessels (→ Liquefied Petroleum Gas, Chap. 5.). Suitable storage tanks for *gasolines, kerosenes,* and *gas oils* are cylindrial floating-roof or fixed-roof tanks (optionally with vapor removal) (→ Automotive Fuels, Chap. 7.). *Heavy fuel oils* and *bitumen* are stored in cylindrical fixed-roof tanks (optionally with gas blanketing).

Underground Storage. Crude oil and liquid (e.g., light heating oil), and gaseous products (LNG) are stored in underground caverns (→ Liquefied Petroleum Gas, Chap. 5.). The underground storage of crudes and liquid products in caverns is usually intended as long term (emergency) storage; caverns for gas are used as buffer storage (→ Natural Gas, Chap. 4.2.2.).

Subsea Storage. Crude oils (from offshore production) and hydrocarbon condensates (from offshore separation) are stored in undersea tanks.

Transport of Crude Oils and Products. Crude oils and bulk (mass) products are normally transported by large tankers and pipelines. Finished products are usually transported by smaller tankers and river barges, product pipelines, rail tank cars, and road tank trucks.

1. Introduction

Oil shale is a sedimentary rock that contains a considerable proportion of solid organic material embedded in a matrix of fine inorganic minerals. Other sedimentary rocks, too, contain organic substances, but the name oil shale suggests that it releases a considerable quantity of oil when processed appropriately. Many rocks, although they satisfy the definition of oil shale, are not true shales geologically.

To recover the oil from the shale, its organic portion – termed kerogen – must be decomposed thermally. This thermal decomposition, known as retorting, converts the solid organic material of the shale into liquid and gaseous fractions and a solid carbonaceous residue. The *liquid fraction*, the so-called shale oil, consists of condensable hydrocarbons (C_{5+}) and small quantities of decomposition water. The *gaseous product* is a mixture of carbon monoxide, carbon dioxide, hydrogen, nitrogen, hydrogen sulfide, methane, and other hydrocarbons (C_{4-}). The *carbonaceous residue* – a cokelike material – is obtained in a mixture with the inorganic minerals of the original oil shale.

Oil shale normally contains fewer organic and more inorganic substances than various types of coal. The organic contents of oil shale often account for $<10\,\%$ of the total mass, whereas coal usually contains ≥ 75 wt % organic substances in terms of water-free material.

A major difference between oil shale and coal lies in the fact that the organic compounds of shale are essentially insoluble in organic solvents (e.g., toluene). Bituminous rocks, oil chalk, tar sands, etc., are therefore not included among oil shales.

The molar ratio of hydrogen to carbon in the organic substances in oil shale is higher than that of the pure organic component of various types of coal. The retorting of oil shale normally yields a higher amount of oil than the pyrolysis of a coal sample containing an equivalent amount of organic material. Unlike coal, oil shales have up to now been less investigated, and no generally accepted classification system exists. For this reason, the names given to oil shales of different origins rarely provide a clear indication of their qualities or types. In addition to general descriptions such as bituminous shale or kerogenic rock, the names may relate the material to a certain deposit or area (e.g., algal shale, paper coal, coorongite, ichthyol shale, kukersite, marahunite, posidonian shale, fetid shale, tasmanite, or torbanite).

The organic component of the world's oil shale deposits is a fossil source of energy that is second in abundance only to coal. Despite the large oil shale deposits, fuel production from shale has so far been uneconomical and hence insignificant. Whenever oil shale retorting plants were built, it was due to abnormal conditions such as a scarcity of conventional fuels because of war or heavy government subsidies. However, as the reserves of conventional crude oil gradually decrease, oil production from shale may become necessary and justifiable for economic reasons.

2. Origin and Properties of Oil Shale

2.1. Origin, Stratification

Oil shale originates from a syngenetic accumulation of bituminous plant components which settled as gyttja (sapropel) in marine, paralic, or limnic basins. Unlike coal, it does not contain any humic matter. Oil shale is found in all geologic strata from the Cambrian to the Tertiary. Many deposits exhibit an annual stratification of sediments that gives them a shalelike appearance. In some rocks, these annual strata are very thin. Some are rich in organic substances; others contain few. In most oil shale, the individual particles are very small; their diameter often does not exceed 200 µm.

The most frequently found inorganic minerals in oil shale deposits are quartz, feldspar, various clays, and carbonates such as calcium carbonate and magnesium carbonate. Other minerals, which have apparently been formed in situ within the sediments, consist of the sulfides of iron, copper, and other metals and of certain sodium salts. Table 1 shows the mineral composition of Green River oil shale.

Table 1. Mineral composition of the inorganic component of North American oil shale (Green River)

Mineral	Chemical formula	Content, wt %
Dolomite	$CaMg(CO_3)_2$	32 – 33
Limestone	$CaCO_3$	16 – 20
Quartz	SiO_2	10 – 15
Clays (illite)	$K_2O \cdot 3\,Al_2O_3 \cdot 6\,SiO_2 \cdot 2\,H_2O$	11 – 19
Orthoclase (adular)	$KAlSi_3O_8$	4 – 6
Plagioclase (albite)	$NaAlSi_3O_8 \cdot CaAl_2Si_2O_8$	10 – 12
Zeolites (analcime)	$NaAlSi_2O_6 \cdot H_2O$	1 – 7
Pyrite, marcasite	FeS_2	1 – 3

Traces of numerous metals including uranium, vanadium, arsenic, and zinc are also common. Phosphate-bearing oil shale of marine origin contains fluorine and uranium; the latter is often also found in nonphosphate oil shales. Sodium salts occur as interspersed crystals and also, in a few cases, in the form of salt deposits embedded in the oil shale; these constitute valuable salt reserves.

2.2. Physical Properties

The physical properties of oil shales differ widely. Discrete layers are frequently found in the shale, and many of these rocks are brittle and cleave easily along the laminate boundaries. Other oil shales are very hard and compact, although a stratification pattern is clearly recognizable. The density of the organic matter in the shale is generally on the order of 1.0 g/cm^3, whereas the inorganic minerals have characteristic densities of, for instance, 2.6 g/cm^3 in the case of feldspar and quartz, and 5.0 g/cm^3 in the case of pyrite. Owing to the differences in the specific masses of organic and inorganic components, high-grade (i.e., high organic content) oil shales have a lower density than low-grade ones. The physical properties of low-grade oil shales resemble those of the inorganic rock components. High-grade oil shales are dark colored because of their relatively high organic content. Important physical properties of oil shales are listed in Table 2 (see next page).

At room temperature, the solubility of kerogen is low in most inorganic and organic solvents. Kerogen solubility increases with increasing temperature, but a noticeable effect is not achieved until the temperature has reached a level at which the chemical links in the kerogen begin to break up. Because of the extremely low tendency of kerogen to dissolve or to swell noticeably – except during thermal decomposition – a rigid structure is assumed [3,4].

2.3. Chemical Composition

To be of economic interest today, oil shale should contain at least 10 % organic material. In most cases, economic interest focuses on the kerogen.

Table 2. Physical properties of oil shale (dry)

	Moisture, %	Gross calorific value, kJ/kg	Grinding index, Hardgrove	Bulk density, g/cm³	Density, g/cm³	Ash melting point, °C
Schandelah (Germany)	3–4	4800	76	1.0–1.2		
Dotternhausen (Germany)	4–5	2900–3800	58	1.2–1.3	2.15–2.20	1150
Kvarntorp (Sweden)	1–2	9000		2.1

Timahdit (Morocco)	6–7	5700	69	1.0–1.2		1180
Green River (United States)	0.5–1.5	6500	43	1.2–1.4	2.1–2.3	1300
Irati (Brazil)	2–5	5200	68		2.3	
Fushun (China)	5	3350–6100			2.3	
Maoming (China)	15–18	5600	62	0.9–1.0		
El Lajjun (Jordan)	4	6900	73	1.0–1.1		1260
Rundle (Australia)	20	5000–6600	60	0.85–0.95		

However, in individual cases the shale may also be processed for all or part of its mineral content; thus low-grade oil shales may also be exploited.

The character of the kerogens in various oil-bearing strata is so complex that it is difficult to describe, and no exact classification has been developed so far. When the kerogen was formed from spores, algae, and other organic matter, conditions strongly favored decomposition. Thus, the properties of kerogen predecessors are largely unknown. Kerogen may generally be described as a mineraloid with a high molecular mass whose composition varies greatly from one deposit to the next. Its major elements are carbon, hydrogen, nitrogen, sulfur, and oxygen, which form heterogeneous macromolecules consisting of aromatic and polycyclic condensed rings with aliphatic side chains of varying lengths linked weakly to them. These side chains themselves are cross-linked to other aliphatic chains via oxygen or sulfur atoms.

Table 3 shows the elemental analysis of typical fossil and recent organic substances along with their C/H mass ratios. In comparison to most other basic organic substances, the C/H ratio of the shale kerogens is relatively low. The same is also true also for shale oil (see Table 8). Consequently, less hydrogen must be added to these hydrocarbons at the refining stage to obtain products such as fuel oil or gasoline. This

Table 3. Elemental analyses and C/H ratios of typical samples of kerogens, crude oil, bitumen from tar sands, wood, peat, and coal

* Moisture, as analyzed, does not represent in situ moisture.
** Ash analysis yielded the following figures in wt %: 24.0 CaO, 38.4 SiO_2, 13.8 Al_2O_3, 6.6 Fe_2O_3, 9.7 SO_3, 2.9 MgO, 2.1 K_2O, 0.7 Na_2O, 0.8 TiO_2, 0.4 P_2O_5, 0.1 BaO.

fact, along with the relative ease with which oil can be produced from oil shale, gives it an edge over coal as a raw material for the production of liquid fuels.

In the Fischer assay (common analysis method for oil shales and coals), oil shale is slowly heated to 520 °C and pyrolyzed, and the masses of the resulting water, oil, gas, and residue are measured. Some results of Fischer assays from oil shales are summarized in Table 4.

3. World Resources and Deposits

Oil shale deposits are found on all continents, but no quantitative figures of total deposits worldwide have been compiled as yet. Even in areas with highly promising deposits, resources have generally been investigated very little. Consequently, the estimates are inaccurate and differ widely in some cases. The data on oil shale deposits in Table 5 were compiled by BURGER from various sources [5] and refer also to estimates made by DUNCAN [6]. They make no pretense of completeness.

Table 5. Estimate of known shale oil reserves from oil shale yielding more than 42 L of oil per tonne [5] (only deposits containing $>50\times10^6$ m^3 of shale oil are listed)

Location of reserves	Amount, 10^6 m^3
United States	
Rocky Mountains	318 000
Eastern areas	32 000
Brazil	
Irati	127 000
Paraiba	320
Australia

Other known deposits in various countries	209

* Rough estimate for high-grade oil shale (>100 L/t).

3.1. Europe

3.1.1. Western Europe

Western Europe has a large number of oil shale deposits dating back to different geological periods. Most of them are small. Of more than regional importance is the marine Liassic formation in Spain, France, Belgium, Germany, and the United Kingdom, which contains oil shale

deposits. Information about these deposits is still fragmentary [7, 8]. As a rule, *marine shales* cover large areas, but their layer thickness is relatively small and they contain only moderate amounts of oil. *Paralic shales* consist mostly of thin layers with higher oil content. They are frequently found in the immediate neighborhood of humic formations. *Limnic deposits* are limited in area but may be of considerable thickness with high oil content.

Germany. Germany has relatively small deposits; posidonian shale (Liassic) is commercially exploited near Balingen. The largest deposit, Schandelah (Lower Saxony), contains 2×10^9 t of oil shale with an oil content of about 6 wt %. The Nördlinger Ries is presumed to contain 2×10^9 t of oil shale. Major quantities of posidonian shale occur in northern and southern Germany at greater depths [9]. A tertiary limnic "paper coal" deposit (Messel, Hesse) has been largely exhausted but is still of great interest to paleontologists [10].

Sweden. Sweden has Cambrian–Silurian deposits of 10-m thickness near Kvarntorp. Their appreciable uranium content may become commercially interesting.

United Kingdom. Seams of oil shale occur in 1800-m Carbonian strata west of Edinburgh. The deposit is mined down to 300-m depth. Kerogen-holding Liassic strata with possibly higher oil contents than those in Scotland are widespread in England [11].

France. France has major Permian deposits: Autun, Aumance (mined for 100 years), Ceverac-le-Chateau, and Creveney.

Spain. A Carbonian oil shale near Puertollano was exploited industrially for about 40 years.

Italy. In Sicily, shale deposits exist that contain ca. 6×10^9 t of oil.

3.1.2. Eastern Europe

In Eastern Europe, oil shale deposits occur mainly in Yugoslavia, Bulgaria, and the Soviet Union. Smaller deposits are also found in Czechoslovakia, Albania, and Greece.

Yugoslavia. Oligocene limnic oil shale is found near Alexinac, Serbia. Its thickness is 80 – 120 m, containing 10 – 15 wt % oil (max. 25 wt %); the total shale deposits amount to ca. 2×10^9 t.

Bulgaria. Oil shale deposits are found in Krassawa (some 50×10^6 t recoverable by opencast mining) and Stara Sagora (thickness 50 – 70 m; 4×10^9 t of oil shale recoverable by opencast mining, containing 4 – 6 wt % oil).

Former Soviet Union. Some 50 oil shale areas are known [12], the largest in the Baltic region and the Volga basin. The Baltic deposits dating from the Ordovician period (kukersite) have oil contents of ca. 20 wt %. They have been commercially exploited since 1916. The recoverable reserves are ca. 2×10^9 t.

3.2. America

Canada. Shale with low oil content occurs in all Canadian provinces; its exploitation is presumably not cost effective.

United States. Deposits with very high oil contents are found in the Green River formation in the Rocky Mountain states of Colorado, Utah, and Wyoming. Their oil content is ca. 10 wt %. The deposits cover ca. 20 000 km^2 and are ca. 30 m thick. Colorado also has deposits with a thickness up to 300 m. This is a low-grade oil shale covering some 50 000 km^2; Utah has deposits with ca. 9 wt % oil content but measure only 10 – 20 m in thickness. Thin Devonian oil shale layers at great depths are found in the eastern United States.

Alaska has little-known deposits dating from various periods [13].

Brazil. Brazil's largest and best-known deposit is the Permian Irati formation. Other low-grade oil shale deposits from the Cretaceous and Tertiary periods are found in various provinces [14].

Oil shale deposits also occur in other South American countries.

3.3. Asia

Oil shale is found in Turkey, Syria [15], Israel [16–18], Lebanon (very high oil contents), and Iraq.

Jordan. High-grade oil shales have been found at El Lajjun (20 km^2 with 130×10^6 m^3 of oil and 10 wt % oil content). Other deposits have been reported (e.g., at Sultani).

Thailand. Particularly high-grade oil shales containing ca. 20 – 25 wt % oil in four seams of low thickness are found in an area of ca. 28 km^2. Some 400×10^6 t of oil are confirmed in Mae Sod. However, their average grade is low (5 wt %).

China. Oil shale deposits occur near Maoming and Fushun; the latter is 100 – 200 -m thick and situated above a very thick coal deposit. Only about 3.5 wt % of oil is obtained by processing the shale.

3.4. Africa

Morocco. Deposits exist near Timahdit and Tarfaya. According to reliable estimates they contain 2×10^9 t and 4×10^9 t, with 7.5 and 5 wt % of oil, respectively.

Zaire. Several layers are spread over ca. 14 000 km^2, with a total thickness of ca. 10 m, that contain oil at a concentration of more than 100 L/t. Estimated reserves are 15×10^9 t of oil.

South Africa. Transvaal has oil shale (torbanite) of very high quality (20 wt % oil) and a seam thickness of ca. 2 m, e.g., near Ermelo and Krill [the deposit at Ermelo was mined and retorted by the South African Torbanite Mining and Refining Co. (SATMAR) for 25 years]. More recent studies have concentrated around the deposit near Krill (15×10^6 m^3 of oil).

3.5. Australia and New Zealand

Economically important oil shale deposits are found in various parts of *Australia*. Recoverable oil reserves in Queensland are estimated at 4.3×10^9 m^3. Major reserves in Queensland are Condor and Rundle.

Little-known deposits from the Tertiary period exist in *New Zealand*.

4. Present Exploitation

Oil shale industries were founded over the last 100 years in Germany, Scotland, Sweden, France, Spain, South Africa, and Australia, but all of them closed after a while. Only two countries – the former Soviet Union and the People's Republic of China – succeeded in setting up oil shale industries that are still processing, respectively, ca. 24×10^6 and 40×10^6 t of oil shale annually. The United States and Brazil, where oil shale reserves are most abundant and richest in oil, have developed oil shale retorting technology to the prototype stage (Union Oil, Petrobras).

Germany produced small quantities of high-sulfur shale oil for medical purposes centuries ago. Industrial oil shale retorting can be traced back to the middle of the last century. Its origins lay in Swabia. Only the Dotternhausen cement works in Germany still uses some 700 t/d of oil shale on a commercial basis. At that factory, fine-grained shale is burned in a fluidized bed (Rohrbach – Lurgi process) to generate energy and produce a residue that is used as an additive in cement production.

A description of the Swedish oil shale industry is given in [19]. Operations were discontinued in 1963. Considerable quantities of shale oil were also produced in Scotland, Spain, and France.

In the lands that later constituted the former Soviet Union, oil shale was initially used as a *fuel*. Retorts were employed for the first time in Estonia in 1925; they were followed by indirectly heated rotary kiln retorts and tunnel kilns with rinse gas heating systems [20]. In 1940, ca. 1.9×10^6 t/a of oil shale was processed in Estonia, 0.4×10^6 t/a in the Leningrad area, and 0.3×10^6 t/a in the Volga basin. Most of these oil shale plants were destroyed during World War II. Reconstruction began shortly after the war and the quantities of oil shale processed in the former Soviet Union grew steadily [21] (quantities in 10^6 t/a).

1945	1950	1955	1960	1965
1.384	4.716	10.793	14.148	21.259

Among these totals, the Estonian oil shale industry accounted for ca. 70 %. Growth trends in the oil shale industry in the Soviet Union are shown in Table 6 [22].

Table 6. Growth of oil shale industries in the Soviet Union (percentage of annual production in 1958 or in the first year of production)

Product	1958	1960	1965	1970	1975
Town gas	100	109	125	135	140
Shale oil	100	119	147	160	180
Aromatic hydrocarbons			419∗	691	1156
Tanning agent		100	178	472	722
Synthetic resins and plastics			500∗	1067	1104
Electrode coke			100	861	1491
Lacquers	100	100	700	2750	3130
Kerogen-70				1102∗∗	3000

∗ Production started in 1962.
∗∗ Production started in 1966.

In *China*, oil shale plants first went on stream in 1914 in Fushun, Manchuria, along with coal mining operations. The oil shale there constituted the overburden that had to be removed to gain access to a coal deposit of considerable thickness. Currently, two retorting plants with an annual consumption of ca. 9×10^6 t of oil shale are operating in Fushun. The Fushun shale is of poor quality. The richest shale found so far contains about 4.7 wt % oil. Normally, shale with an oil content <3.5 wt % is rejected. The strip mine covers an area of 40 km^2 and belongs to the largest open-pitmines of the world.

The Maoming plant in the Guandong Province started up in 1961 and currently produces ca. 100 000 t of shale oil per year. Production was reduced in recent years from 200 000 t of shale oil annually due to the discovery of crude oil [23].

World oil demand is currently met by a sufficient supply of crude oil. Whenever conventional oil supplies are sufficient, shale oil has not been competitive. However, decreasing reserves and an increasing demand for oil will necessarily lead to an escalation of its price in the future. With this perspective in mind, shale oil produced by modern cost-effective technologies may be expected to be competitive in the medium run. Great efforts have been made for years, especially in the United States, Germany, Brazil, and the Soviet Union, to develop more effective shale oil production processes (see Chap. 7).

5. Mining Methods

Before oil shale can be processed in surface retorting plants, it must be mined and transported to these plants. Mining costs constitute a major share of the total shale oil production costs. Modern commercial oil shale processing plants can be cost effective only if large and highly efficient equipment is used, which keeps the cost per tonne of mined material to a minimum. Prospects are good for the introduction of new processes and equipment to mine oil shale deposits of great thickness that often cover considerable areas.

Either underground or open-pit methods can be used to mine oil shale. The method selected in each particular case depends on the depth and size of the deposit; on topographical, geological, and hydrological considerations; and on environmental questions.

5.1. Underground Mining

Room-and-Pillar System. The room-and-pillar system is appropriate wherever conveniently accessible deposits of great thickness are exploited. With this method, part of the shale is taken out in such a way that underground rooms of regular shape are produced. The remaining shale is left in place as pillars between these rooms to support the overburden.

The pillar and room sizes are determined by the physical properties of the shale and the overburden. This mining method is widely used for ore and coal mining, and has also been employed in oil shale mining operations (e.g., in the United States, South Africa, Australia, and Estonia).

In the *Green River formation* the room-and-pillar system was used to mine oil shale deposits 10 – 30 m thick under an overburden of 50 – 150 m. The rooms had a width of ca. 18 m, leaving square pillars of 18-m side length and 18-m spacing between them in offset rows. In this way, 75 % of the total shale can be mined, whereas 25 % must be left in place as supporting pillars. The advantage of this system is that large power shovels, loaders, and hauling equipment can be used underground.

A major portion of the *Estonian oil shale* is currently mined by the room-and-pillar system, which requires a great deal less manual work than former longwall methods.

Longwall Method. Most underground mines in the Estonian oil shale area used the longwall method before the room-and-pillar system was introduced in 1958. Typical face lengths were 85 – 90 m. To facilitate mechanical cutting along the face, holes had to be drilled and explosives used. A lot more manual work is required to load the material, advance the conveying system, and support the roof. Longwall mining was also used in a few oil shale mines in Scotland.

New Underground Mining Concepts. In extremely thick oil shale deposits, low-cost large-capacity mining methods such as block caving, stoping and gobbing, space stoping, or a modified room-and-pillar method can be used.

5.2. Above Ground Mining

Above Ground mining is highly efficient, and mining losses are kept to a minimum. The most important methods are open-pit and strip mining. These methods are employed at present to work oil shale deposits in Estonia, Manchuria, and Brazil.

Open-Pit Mining. In an open-pit mine, the overburden is stripped off and hauled away to the waste dump in the voided part of the mine by trucks, pit railways, or belt conveyors. The exposed shale is then mechanically excavated and hauled off. The type of equipment used depends crucially on the geology and mechanical properties of the overburden and shale. Soft materials are conveniently removed by bucket-wheel excavators, whereas hard rocks require power shovels and scrapers and possible blasting.

Strip Mining. Strip mining employs dragline excavators that are shifted only rarely from one location to another. They discharge the excavated overburden promptly by swiveling the full bucket from the trenchlike digging area to the dumping area. No overburden hauling facilities are thus required. Shale is excavated from a strip mine in the same way as from an open pit.

Newly designed mining systems that are more cost effective or permit opencast mining of deeper shale deposits are currently being tested.

6. Shale Preparation

Unless the oil shale is used in situ, it must be upgraded before it can be retorted, gasified, or burned. This means at least that the shale must be classified and crushed. Raw shale with high moisture content may also need to be dried. Suitable dryers for high throughputs are well known (e.g., rotary kilns and entrained-flow dryers).

High-grade oil shales have a lower density than low-grade shales, so that they can be enriched in settlers, sink and float equipment, etc. Selective comminution may be another method to be considered, because rich and lean shales often differ in their grinding properties. There is doubt whether enrichment processes can ever become important, because oil shale is a low-grade raw material and processing may be expected to be cost effective only for extremely high throughputs. Oil shales that are so lean they must be enriched are of no economic interest in the short or medium run.

The *Brazilian* Petrosix retort – a shaft furnace – requires a feed with a particle size of 6 – 80 mm. To prepare it for this retort, the oil shale is gently comminuted and screened.

At Fushun (People's Republic of China), oil shale containing less than 3.5 wt % oil is rejected in the mine. Fine-grained shale is screened off and kept out of the retorts as well.

In Estonia, shale enrichment is relatively common because of the special quality of the kukersite shale. Settlers, slurry separators, air classifiers, flotators, and selective comminution equipment are used for this purpose.

7. Pyrolysis

7.1. Definition and Kinetics

In pyrolysis an organic substance is thermally converted by heating in the absence of oxygen. The pyrolysis of kerogen yields shale oil, reaction water, noncondensable gases, and a carbonaceous residue. The inorganic mineral matrix of the shale is retained in the form of ash or spent shale.

Oil shale pyrolysis begins at relatively low temperature (200 °C), but proceeds more rapidly and more completely at higher temperature (500 – 600 °C). Various gases and vapors are produced from the organic materials during the process.

Once gas generation ceases, an unburned carbonaceous residue remains that sticks to the solid inorganic material of the original oil shale. The gases and vapors leaving the retort are cooled to condense the oils and reaction water.

The kinetics of oil shale pyrolysis has been investigated, and the following reaction sequence for Colorado oil shale has been described [24, 25]. First, kerogen is broken down to produce bitumen, gases (condensable hydrocarbons and other organic compounds), and a carbonaceous residue. The bitumen is then decomposed further in a second step, yielding other gaseous and liquid hydrocarbons.

The kinetics of shale oil formation can be described by two sequential first-order reactions [26]:

$$K \xrightarrow{k_1} B + G_1 + C_1$$

$$B \xrightarrow{k_2} A + G_2 + C_2$$

where K is kerogen, B is bitumen, A denotes oil, G_1 and G_2 are gaseous products, C_1 and C_2 carbonaceous residues, k_1 is the rate constant of kerogen decomposition, and k_2 is the rate constant of bitumen decomposition.

Kinetic equations were derived for the decomposition of kerogen and for the formation of bitumen and oil. The corresponding rate constants were determined by integrating and combining the equations: above 400 °C the decomposition of kerogen is the rate-determining step; below 400 °C the decomposition of bitumen is rate determining. The low activation energy of 44.56 kJ/mol for the first reaction proves that kerogen decomposition involves the cleavage of relatively weak chemical bonds, whereas the activation energy of 177.6 kJ/mol required for the second reaction indicates that much stronger chemical bonds must be broken for bitumen decomposition.

Many studies have focused on the amount of gaseous and solid products resulting from each of the two reactions. One interpretation is that most of the carbonaceous residue is formed during the kerogen-to-bitumen conversion, whereas most of the gas is evolved during the bitumen-to-oil conversion, although small amounts of hydrogen sulfide and carbon dioxide precede hydrocarbon evolution (e.g., with Australian kerogen).

Since liquid hydrocarbons historically have had a higher economic value than gaseous or solid hydrocarbons, special attention has been directed toward maximizing oil yields. Oil yield from shale is decreased by coking, cracking, and combustion.

Coking is a liquid-phase condensation or polymerization reaction that results in the fusion of two or more molecular species, with ultimate formation of a high-polymer carbonaceous product and minor amounts of lower molecular mass gases and liquids.

Cracking involves vapor-phase bond-fission reactions that eventually lead to a distribution of smaller molecular units plus, possibly, a certain amount of carbonaceous residue. An important difference between coking and cracking is the molecular mass distribution of the products. Cracking reactions lead to a higher yield of hydrocarbons with a lower molecular mass (CH_4, C_2H_4, etc.), whereas coking reactions produce mainly a high-polymer carbonaceous residue.

Combustion is for the most part a mass-transfer-limited reaction that occurs if both oxygen and organic material are present at high temperature. Under fuel-rich conditions, combustion and cracking become closely related. Oil that is not combusted at these temperatures will undergo thermal cracking. In addition, oxygen is a good initiator of free-radical cracking, because it is a free radical.

The physical description of oil production from bitumen is as follows. Bitumen decomposes to oil, gas, and a carbonaceous residue. The oil exists in two physical states: liquid oil and oil vapor.

In the liquid phase, oil is subjected to two competing processes: vaporization, which leads to the production of oil, and coking, which leads mainly to a carbonaceous residue. To obtain high oil yields, the residence time of the oil in the liquid phase must be kept short to minimize oil coking. This can be accomplished either by high retorting temperatures and high gas sweep rates or by high heating rates. The reason for the in-

crease in oil yield with increasing *heating rate* is twofold. As a result of the kinetics of the reaction the average temperature of the oil evolved depends on the heating rate. Higher heating rates result in the oil being evolved at a higher average temperature; hence a smaller fraction of the oil remains in the liquid phase. Furthermore, higher heating rates increase the rate of oil vaporization and thus reduce liquid-phase coking. These two effects increase oil yield by reducing coke formation.

High retorting temperatures increase liquid yield by decreasing oil coking. However, too high a temperature will decrease oil yield because of secondary vapor-phase oil cracking.

Retorting conditions for oil shale have a significant effect on the properties of the oil. For Colorado oil shale, a decrease in the yield of oil due to *coking* causes an increase in the H/C ratio and a decrease in the nitrogen content of the remaining oil. Associated with the increase in hydrogen content is a lower density. In contrast to oil coking, oil *cracking* results in a decrease in the H/C ratio and an increase in the nitrogen content of the remaining oil. Also, the pour point of the oil (which depends on the content of long-chain alkanes) drops sharply with increased degree of cracking.

These differing trends with coking and cracking can be easily understood. Oil coking is most likely caused by condensation and polymerization reactions involving nitrogen-containing compounds. Since nitrogen is contained mostly in aromatic rings, removal of these hydrogen-deficient compounds causes an increase in the H/C ratio. In addition, the lower temperatures for oil evolution associated with *coking* cause a decrease in the alkene-to-alkane ratios in the oil.

In contrast, in *oil cracking*, alkanes are converted to alkenes and aromatics. Thus, the H/C ratio in the remaining oil decreases, a result that is most likely a function of both temperature and conversion. In addition, the nitrogen content of the oil increases with cracking, because the aromatic nitrogen compounds in shale oil are resistant to cracking. As the alkanes and alkenes are partially converted to gases, the nitrogen compounds are selectively concentrated. A 50 % conversion, for example, results in roughly a doubling of the nitrogen content.

7.2. Above Ground Retorting Processes

Commercial oil shale retorting plants have been operated in various countries for more than a hundred years, but their design, low thermal efficiency, and insufficient capacity make them noncompetitive under current economic conditions.

A simple design and reliable operation, along with low capital and operating costs, are prerequisites for a modern oil shale retorting process to become an economic success. Yields reaching 100 % of the Fischer assay are desirable; the process should not depend on additional external energy supplies, should be continuous, and should be environmentally benign.

Classification of Retort Types. Retorting of oil shale entails the heating of a large mass of nonproductive rock to pyrolyze the kerogen. The principal aim in retort design is to accomplish this heating at low cost by using the least amount of energy. Thus, the method of heat transfer to the raw shale provides a convenient way to classify retorts. Three different methods can be distinguished.

Class 1 (Indirectly Gas-Heated Retorts). Heat is transferred to the shale through a wall. A simple example of this type of retort is the Fischer assay apparatus used to measure shale quality. The Pumpherston retort, the Salermo retort, and the Davidson retort are typical examples of class 1 oil shale retorts. This retort type is not being developed further because of the small unit capacity, expensive heat transfer, and low thermal efficiency of the method.

Class 2 (Directly Gas-Heated Retorts). Heat is transferred by passing hot gases directly through the shale, mostly in a vertical shaft kiln. This class can be subdivided into the following:

In class 2 a (internal combustion mode), hot gases are generated by the combustion of residual carbon or a portion of the hydrocarbon product within the retort. Examples of this type are the Fushun retort, the Paraho retort, the Lurgi Spuelgas kiln, the Union A retort, the Superior retort, the Kiviter retort, and the Lurgi–Schweitzer kiln. This method of heat transfer is inexpensive and allows relatively low-cost retort construction. However, the yield of hydrocarbons is lower than with other methods, and the retort gas is largely diluted by combustion products and nitrogen from the combustion air.

In class 2 b (external combustion mode), the gases are externally heated in a gas heater (e.g., by combustion of a portion of the hydrocarbon product). Examples are the Union B retort, the Petrosix retort, and the Lurgi tunnel oven. These retorts require an external gas heater, which may be expensive and lead to operating problems. Hydrocarbon recovery is higher than in the case of class 2 a retorts, and the gas from the retort has a high calorific value because it does not contain combustion products. In contrast, the thermal efficiency is lower because the residual carbon in the spent shale is not utilized in most cases.

Common to most class 2 retorts are (1) their inability to process shale fines and (2) increasing problems with uniform shale-size and gas distribution through the retort shaft area with increasing retort size (i.e., capacity).

Class 3 (Directly Solids-Heated Retort). Heat is transferred by mixing hot solid heat carriers with the fresh shale. This method involves a somewhat more complex heat carrier circulation system but has the advantages of:

- High oil yields due to high heating rates (flash retorting),
- Undiluted product gas and vapors,
- Direct use of spent shale carbon as fuel if spent shale is used as the heat carrier,
- Use of fine granular shale with no minimal size restriction, and
- Easy scaleup to very large unit capacities.

Examples of this retort type are the Lurgi – Ruhrgas retort, the Tosco II retort, the Galother retort, and the Chevron STB retort.

7.2.1. Class 1 (Indirectly Gas-Heated) Retorts

Class 1 retorts were used mainly before 1960. They generally have the advantage of producing an undiluted gas and vapor product stream with few restrictions on the grain size of the feed oil shale. However, a low unit throughput, high specific investment cost, and a low thermal efficiency, have hindered further development of retorting technologies based on this heat-transfer principle.

Pumpherston Retort. The Pumpherston retort emerged as the most successful retort of the Scottish oil shale industry in the second half of the 19th century. It was also widely applied, for example, in France (more than 200 retorts in operation by 1905) and Spain (Puertollano). Pumpherston retorts were mounted in huge banks because of their limited throughput. In 1947 the Westwood plant in Scotland consisted of two benches with 52 retorts each, backed up to one another in pairs. Total capacity of the plant was 1040 t/d (i.e., 10 t/d per retort). Shale processed in this plant in 1947 had an average oil yield assay of 21.4 gallons per ton (ca. 90 L/t) of feed. Daily oil production was about 530 barrels.

Figure 1. Single Pumpherston retort (1947)
a) Waste-heat boiler; b) Cast-iron retort; c) Brick retort; d) Scrubber; e) Condenser

Figure 1 is a schematic of a single Pumpherston retort in 1947. Above each pair of retorts was a large hopper carrying a 30-h oil shale supply for the two retorts. This fed into the small shale hopper indicated at the top of the retort in Figure 1. Each retort consisted of a cast-iron section 4.3 m long and an oval-shaped and tapered brick section 6.1 m long. The cast-iron part of the retort was surrounded by masonry enclosing a free space for heating the retorts externally by burning noncondensable shale gas. The crushed shale entered the retort at the top, flowed downward by gravity, and emerged at the bottom through a discharge hopper with water-sealed doors. As indicated in Figure 1, shale gas

and air were supplied, and the gas was burned at the bottom of the retort. The combustion products passed upward around the cast-iron section to preheat the entering shale. Residual heat in the flue gas was recovered in the waste-heat boiler. Steam from this waste-heat boiler together with a regulated amount of air was injected into the interior of the retort at the bottom. The steam generated ammonia and swept the oil vapors upward. In addition, at the high temperature maintained in the lower part of the retort (1000 °C), air and steam reacted with the residual carbon to supply much of the heat required in the retorting process. Virtually all of the residual carbon was consumed.

This injection of air at the bottom of the retort changed the process from an indirectly gas-heated (class 1) to a partially directly gas-heated (class 2 a) mode and increased each retort's throughput capacity from ca. 4 to 10 t/d, permitting the use of lower-grade oil shale. Flow of shale through the retort was controlled by the rate of removal of spent shale at the bottom of the retort. Heat was recovered from the exiting spent shale. Spent shale was discarded in large piles called "bings," still in evidence throughout the area of oil shale processing in Scotland. Although some spent shale was made into brick by adding lime and steam-curing the resulting bricks, no major use for the spent oil shale was ever found.

Gases and oil vapors leaving the top of the Pumpherston retort passed through preliminary water sprays and then through water-cooled, multiple condensers. Most of the ammonia remained in the condensed water, but the gases were further scrubbed first with water to absorb the rest of the ammonia and then with gas oil to remove the remaining naphtha. The condensed oil and ammonia-containing water separated easily. The water was processed in an ammonia recovery plant on site. The uncondensed gas used in retorting amounted to about 290 m^3/t (STP) of shale and had a heating value of only about 5600 kJ/m^3, primarily because of dilution with inert gases and carbon dioxide. However, the Westwood Pumpherston plant was energy self-sufficient because the residual carbon was burned in the retorts. Each tonne of shale processed produced about 0.5 barrel of oil and 12 kg of ammonium sulfate. For processing, the oil was shipped to oil refineries serving several retort plants. In [27] the following product distribution is given (in wt %):

Motor spirit (octane number 57)	19.00
Diesel fuel	52.00
Paraffin wax	9.00
Tar (including acids and bases)	11.60
Coke (1 % ash)	2.75
Resin	1.00
Loss (by difference)	4.65

All products found a ready market in Scotland. Acid was recovered from the acid tars and used in ammonium sulfate production. The tars produced were used as refinery fuel. The Scottish oil shale industry closed down in 1963 due to the competition of cheap, imported crude oil, and the depletion of high-grade oil shale reserves.

Davidson Retort. The Davidson retort (see Fig. 2) consisted of a cylinder 1.2 m in diameter and 23 m long, sloped slightly from shale inlet to shale outlet. This cylinder rotated slowly in a brick-lined heating chamber. Heat was generated in a combustion chamber at the outlet end of the retort. The gaseous combustion products

Figure 2. Davidson retort

were passed along a flue to a row of ports into the heating chambers around the rotating retort. Heat admitted to the heating chambers was controlled at the ports. The Davidson retorts normally operated with two temperature zones: a drying and preheating section kept at ca. 400 °C in the first third of the retort, and a retorting zone kept at ca. 630 °C. The capacity of each Davidson retort was about 27 t/d. This feed rate was not very flexible. If too little feed was admitted, the charge would slide instead of tumble, and the shale would tend to stick together in cakes. If too much was fed in, the evolution of oil would not be complete. Spent shale was discharged through a double-door arrangement to prevent air entry into the retort. Each Davidson retort produced about 38 barrels of oil per day at a recovery of about 90 % of Fischer assay. The electrical energy needed to turn the huge retort tube and to meet other requirements was 8 kW · h/t. Gas energy input to the Davidson retort was 2600 kJ/t. In 1947 the carbon on the Davidson spent shale was discarded because of the cheap coal available.

Davidson retorts had been operated in Estonia as early as 1932, and Davidson had several patents on variations.

Salermo Retort. In 1935, SATMAR started retort operation near Ermelo, Transvaal. In the Salermo retort, small oil shale particles were progressively shoveled through a series of semicircular troughs heated from the underside. This retort, called Salermo in South Africa, probably originated from the retort patented by P. M. Salerni in 1928.

Figure 3. Trough and shovel operation in Salermo retort

Figure 3 is a schematic view of the troughs to illustrate shale travel and operation of the paddles. The SATMAR Salermo retort consisted of 36 semicircular mild-steel troughs 0.4 m in diameter and 2.3 m long. These troughs formed the bottom of the retort. Side, end, and top cover plates isolated the troughs from the atmosphere. A rod with 16 T-shaped paddles attached (Fig. 3) revolved in each trough.

Each rod was rotated from the outside at 5 rpm. Shale entered the retort, and was agitated and moved from trough to trough by paddle rotation. Below the first nine troughs was a combustion chamber leading to flues that distributed heat along the length of the retort. Noncondensable shale gas was the primary fuel, supplemented by producer gas. As the oil shale was shoveled from trough to trough, it was gradually heated. The first troughs were dryers and preheaters. By trough 14 the shale temperature had reached 300 °C, and at the discharge it reached 450 – 500 °C. Small amounts of gas were added and burned along the flues to help raise and maintain the higher temperature toward the discharge end. Evolving gases were led off to condensers for separation.

Each Salermo retort processed 70 t/d on average. During an operating day, each retort produced about 90 barrels (13 t) of oil. The electric power required was about 3.5 kW · h/t. The total heat input to the retort, primarily from 37-MJ/m^3 retort gas but supplemented by producer gas, was about 2.1×10^6 MJ/t of shale. A retort operated continuously for 140 d and was then cooled, overhauled, and reheated, a process that took about 20 d. Recovery was about 90 % of Fischer assay, or about 50 gallons per ton (210 L/t) of oil. Similar to the spent shale from the Davidson retort, Salermo spent shale contained large quantities (up to 40 %) of carbon. Because waste coal was mined with the shale, no effort was made to recover the energy content of this carbon.

There is still one Salermo retort in operation in Clerbagnoix (France) that produces high-sulfur shale oil. This oil is used for the production of ichthyol pharmaceuticals.

In 1947 the SATMAR retorting plant consisted of four Davidson retorts, ten Salermo retorts, an oil shale crushing and screening plant, and seven gas producers gasifying coal to supply fuel gas. The Davidson retorts received ≥25-mm material, whereas all smaller material

was fed to the Salermo retorts. No fines were discarded. Both the Davidson and the Salermo retorts were externally heated by using noncondensable gases from the oil shale supplemented by producer gas generated from coal. The company persisted and even paid dividends until it-mined itself out of existence in about 1962, by which time it had exhausted its oil shale (torbanite) resources.

7.2.2. Class 2 (Directly Gas-Heated) Retorts

Class 2 retorts have found worldwide application because of their simple shaft kiln design.

Class 2 a Retorts. Class 2 a retorts are heated by hot flue gas produced either by combustion of spent shale carbon through injection of air into the lower retort section or by combustion of some product gas and oil in a combustion chamber adjacent to the retort. They operate with *internal combustion*.

Paraho Retort. The Paraho retort (see Fig. 4) was developed in the 1970s on the basis of available lime kiln technology and the earlier gas combustion retort by the Paraho Development Corp. (United States). It is a typical vertical shaft kiln.

Figure 4. Paraho retort
a) Retort; b) Oil – gas separator; c) Recycle gas blower; d) Air blower

Raw shale, crushed and screened to a feed size of 0.6 – 8 cm, is conveyed to the feed system on top of the retort. In a continuous moving bed, the shale flows downward consecutively through the mist formation, retorting, combustion, and cooling zones. As the shale descends, heat is efficiently exchanged with a countercurrent flow of recycle gas, which is introduced into the retort at different levels by three specific-purpose gas – air and gas distributors. Near the top of the retort (in the *mist formation zone*), the ambient-temperature shale is warmed by rising hot oil vapors and gas which, in turn, are cooled to form an oil mist that is entrained in the gas.

As the shale continues downward into the *retorting zone*, it is heated by rising hot gases until it reaches about 482 °C, where kerogen is pyrolyzed into oil vapor, gas, and carbonaceous residue. This residue, which remains on the shale, is utilized as a fuel when the shale bed descends into the *combustion zone*, where combustion is achieved by the injection of air (diluted with recycle gas) through the middle and top distributors. This combustion provides the heat for the retort process.

Below the combustion zone the descending shale is cooled to about 149 °C by passage through a stream of cool recycle gas, which is injected into the shale bed by the bottom gas distributor. The cooled retorted shale is discharged at the bottom through the hydraulically operated Paraho grate mechanism, which regulates the rate and uniformity of descent of shale through the retort. Displaced shale drops into a collection hopper and passes through a rotary seal and out of the retort, where it is conveyed to the retorted shale disposal site.

Yield and properties of Colorado oil shale processed by the Paraho retort may be summarized as follows:

Yield	
Shale assay	27.4 gallons per ton (114 L/t)
Retort production	24.4 gallons per ton (102 L/t)
Percent of assay	89 – 94 %
Physical properties	
Specific gravity	21.4 °API (→ Oil Refining)
Density	925 kg/m^3
Viscosity (54 °C)	83 SUS (Saybolt units · second)
Viscosity (99 °C)	48 SUS
Pour point	29 °C
Water	0.3 wt %
Sediment	0.1 mL/100g
Elemental analysis	
Carbon	84.8 wt %

Hydrogen	11.4 wt %
Nitrogen	2.0 wt %
Sulfur	0.6 wt %
Oxygen	1.2 wt %

Lurgi Spuelgas Retort. The Lurgi Spuelgas retort, which had been successfully applied to the carbonization of brown coal briquettes and bituminous lumpy coal in more than 250 units, was modified slightly to make it suitable for retorting oil shale. The kiln (Fig. 5) is of the double rectangular-shaft type and incorporates a drying, retorting, and residual carbon gasification zone through which shale travels from top to bottom. The shale is dried and retorted by recycling product gas (Spuelgas) in counterflow to the shale. The Spuelgas is internally preheated by cooling spent shale in the lower shaft section and heated further by mixing with hot gas from the combustion chamber. This kiln yields a highly diluted gas.

Figure 5. Lurgi Spuelgas retort
a) Drying zone; b) Carbonization zone; c) Cooling zone; d) Burner

In 1944 a 3000-t/d oil shale retorting plant was engineered for Spanish Puertollano oil shale, but Pumpherston retorts were finally installed. In 1958 a 400-t/d kiln including a residual carbon combustion zone was installed near Kisangani for Zaire oil shale. Besides shale oil, spent shale was used by the cement industry. The capacity of a kiln is ca. 500 t/d. Higher capacities involved increasing problems with the uniform distribution of gas and solids through the shaft area of the kiln. Oil yields up to 93 % of the Fischer assay can be obtained by this retort.

Union A Retort. The Union A retort was developed by the Union Oil Company of California in the 1950s. It is also a vertical shaft kiln involving a novel rock pump designed to force raw oil shale up into and through the body of the retort.

The retort (Fig. 6) is shaped like an inverted cone. it admits a crushed shale feed of 6 – 100-mm particle size. In this system, shale moves through the reactor from the bottom upward. A rugged, reliable reciprocating rock pump forces cold feed into the bottom and then further up the retort. Spent shale is discharged over the top of the reactor shell.

Gases flow through the retort downward in countercurrent to the shale. The hottest part is the combustion zone at the top of the retort. There,

Figure 6. Union A retort
a) Crusher; b) Cooler; c) Wetting

near the solids overflow, air is blown into the reaction bed to burn the carbonaceous residue on the spent shale particles. As it moves up the retort, the cold shale is first preheated and then retorted, and finally the carbonaceous material is burned to provide all the heat required for the process. The oil and gases are withdrawn from the bottom of the conical retort.

To date, only one retort of this type with a 1.7-m feed piston and a maximum cone diameter of 5.2 m has been operated. It reached a throughput of ca. 1000 t of shale per day and a yield of about 85 % of the Fischer assay. The retort gases have a low calorific value of 4000 kJ/m^3 (STP).

Dravo/Superior Circular Grate Retort. The Dravo/Superior Circular Grate Retort was initially developed by Superior Oil Co. in the United States during the 1970s. The retort was based on available circular grate technology developed for sintering iron ore pellets. In the 1980s, Dravo took over this development and tested the process in its 220-t/d pilot plant in Cleveland, Ohio.

In the circular grate retort (Fig. 7), hot recycle gas is combusted with air inside the retort. Both the recycle gas and the combustion air are preheated by passage through the traveling spent shale bed, and the spent shale is cooled at the same time. The recycle gas has a low calorific value because of significant dilution by nitrogen from the combustion air. This low-energy gas is burned in special burners above the entering shale bed. The combustion products at 725 – 775 °C carry heat into the shale bed to generate and drive out oil and gas. The oil and gas pass with the gas flow out of the shale bed to the oil recovery system. The traveling grate then moves the shale bed into the *carbon recovery area*. Preheated air (≈200 °C) that directly enters the top of the spent shale bed is used to burn residual carbon. This combustion heats the shale residue. The combustion products join the recycle gas stream. After oil removal, recycle gases at about 100 °C pass through the heated shale residue on the moving track and are heated to 275 – 375 °C. Final cooling of the spent shale is performed by passing ambient air through the traveling bed. Cooled spent shale leaves the retort through a liquid seal. Although this retort is flexible with regard to feed shale size and offers no major scaleup problems, a large-scale unit has not yet been built.

Fushun Retort. The Fushun retort is still being used in the Chinese oil shale industry. Because it has been in operation for 50 years, it has been modified gradually, but the Fushun retort

Figure 7. Dravo/Superior retort (direct heating mode)
a) Heating; b) Carbon recovery; c) Cooling by recycle gas; d) Cooling by air; e) Water seal; f) Oil removal; g) Gas compressor; h) Direct-heating low-BTU burner

was initally modeled after an internally heated retort tested in Estonia. In operation, the Fushun retort strongly resembles the gas-combustion retort, a predecessor of the Paraho retort. The retort used at Fushun and at Maoming is a vertical cylinder about 3 m in diameter and 15 m high. Average oil yield of the shale processed in 1979 was about 6.7 wt % .

Crushed oil shale screened to discard particles <8 mm, which incurs a 15 % loss of fines, is fed into the top of the retort. Operation of the retort is continuous because the shale is progressively dried and heated as it moves downward, reaching retorting temperature in about the middle of the retort. Spent shale moves into the "gasification section," where the residual carbon is burned and gasified by reaction with hot air and steam. The temperature in this section is 700 – 800 °C. The hot gases travel upward to heat the incoming shale, while the remaining ash travels downward to heat the incoming air and water. It then drops into the "ash dish," is cooled to 70 °C, and is removed from the system.

The oil vapors and noncondensable gases leave the top of the retort at 90 – 110 °C and pass to the condenser system. The cooling and recovery system strongly resembles that described for the Scottish Pumpherston plant. In addition to oil, ammonium sulfate is also recovered here. A block of 20 to 25 retorts shares a single condenser system. The evolved gases supply heat to the retort and are also used as an energy source. The plant requires no external energy supply. The oil yield of the entire system is about 60 % of the Fischer assay. Each retort processes about 20 t/d of oil shale.

To obtain 1 t of shale oil at Fushun, the following inputs to the system are required:

Oil shale	40 t
Water	5 – 6 t
Electricity	150 – 170 kW · h
Steam	2 – 3 t

The oil shale industry in the People's Republic of China is the largest in the world.

Kiviter Retort. The Kiviter retort (Fig. 8) was designed in the Estonia to process kukersite shale, which tends to soften and cake during retorting. The size of the feed shale ranges from 25 – 100 mm. The Kiviter retort was apparently developed from the Pintsch retort, which is termed a gas-generation retort in the Soviet Union. The Kiviter retort is a vertical system internally heated by combustion of coke residue and noncondensable shale gas. In many respects it resembles the gas-combustion and thus the Paraho retort. Kiviter units with capacities of 180 – 1000 t/d have been put into commercial operation. The unit has also been tested successfully on low-yield oil shale, which permits faster throughput.

Figure 8. Kiviter retort
a) Oil shale retorting and evacuation chamber; b) Recycle gas inlet; c) Spent-shale discharge device; d) Gas burner; e) Heat carrier, distribution chamber; f) Charging device

Operation of the Kiviter retort is continuous. Raw oil shale enters from the top (Fig. 8) and is heated to the temperatures required to decompose the organic matter. Heat is provided by the rising gases supplemented by recycle gas burned in the heat carrier preparation chamber. The combustion products pass sidewards through the descending shale and carry the oil vapors and evolving gas with them into the collection chamber. From there they are delivered to the condensing system. Additional recycle gas and air are admitted to the chambers near the 900 °C point and heat the shale residue to burn off the coke. Recycle gas entering the bottom of the retort cools the spent shale, which then leaves the retort through a water-sealed discharge system. The Kiviter retort operates on Baltic shales enriched at the mine to an oil yield of 21.3 wt % (233 L/t) and produces the following materials (in kilograms per tonne of wet feed):

Input	
Dry shale	910
Associated water	90
Steam	50
Air	430
Total input	1480
Output	
Shale oil	180
Gas	560
Process water	160
Spent shale	580
Total output	1480

The Kiviter process recovers about 75 % of Fischer assay oil. The electrical energy required by the process is 18 kW · h per tonne of wet feed shale. The gross calorific value of the nitrogen-diluted product gas is 3534 kJ/kg. In the Soviet Union special burners were designed to use this low-energy gas. A large-scale 1000-t/d Kiviter retort was built in Estonia in the late 1970s.

Lurgi – Schweitzer Process. The Lurgi – Schweitzer process was developed in Germany as a low-cost retort during World War II. The principle of this process is the retorting of lumpy low-grade oil shale in a descending gas stream. The retort consists of a cylindrical shaft with no refractory lining and is operated batchwise. After charging, the upper shale layer is ignited like a pipe, and air is sucked through the shale bed from top to bottom, whereby the combustion zone moves slowly downward. The hot gases retort the shale below the combustion zone so that the heat required for the process is produced only by combustion of the residual carbon. On completion of the retorting process, the retort is tilted, discharged, and subsequently recharged. A commercial plant comprising 38 units was installed in 1942 in Württemberg, Germany, and operated until 1949. This process gives a maximum oil yield of 95 % of the Fischer assay.

Class 2 b Retorts. Class 2 b retorts are heated by hot recycled product gas that is reheated in an external (indirectly heated) heat exchanger. These retorts are classified as operating with *external combustion*.

Union B Retort. The Union B retort is very similar to the directly heated Union A retort (Fig. 6). However, it is heated by circulating gases deriving their heat from a recuperative system, whereas the heat required in the Union A retort is generated by internal combustion.

Screened shale particles are fed to two reciprocating rock pumps via a shale oil siphon, and delivered to the bottom of the retort. The shale then moves evenly up the conical part of the retort and is extracted by a special rotating rake from the top. Thereafter, the residue flows into a collecting and cooling system. The top of the retort is covered by a gastight hood that permits an operating pressure of about 1 bar above atmospheric pressure. As in the Union A retort, the condensed oils and vapors are withdrawn from the bed through many vertical slots arranged along the perimeter at the bottom of the cone.

The Union B retort reaches oil yields of about 100 % of the Fischer value and the gas produced has a calorific value of ca. 33 500 kJ/m^3 (STP), because it is not diluted by combustion products. However, the overall thermal efficiency of the process is relatively low (ca. 69 %) because the energy of the carbon in the spent shale (about 4 wt % in the case of Colorado oil shale) is not used. Therefore, Union Oil investigated the addition of a circulating fluidized-bed (CFB) combustor for the spent shale, to increase the thermal efficiency of the overall system.

In 1983, Union Oil commissioned a 10 000 barrel/d Union B retort in Colorado. Because of problems resulting from excessive decrepitation of spent shale in the upper part of the retort, the retort is operated at a lower than design capacity (60 – 80 %). In 1989, however, a high onstream efficiency of ca. 90 % seems to have been achieved. Operation was stopped in 1991 due to currently low crude oil prices.

Petrosix Retort. The Petrosix retort, which was developed in Brazil, is shown in Figure 9. The retort is externally heated to maximize sulfur recovery from the pyritic Irati shale and to avoid agglomeration and sintering problems experienced with directly gas-heated retorts.

Shale sized $\leq$15 cm and blended to uniform grade enters the top of the retort. Hot recycle gas enters the middle of the retort to heat and drive off oil and gas. Hydrogen sulfide is also generated. Heated shale travels downward and is cooled by recycle gas entering the bottom of the retort. The flow rate of the shale through the retort is controlled by the grate discharge mechanism. Spent shale leaves the retort at about 150 °C. It passes through a sampling system that measures discharge flow rate and selects a sample for Fischer assay. The results of the Fischer assay are used as input to the process control sys-

Figure 9. Petrosix retort

tem. Processed shale enters one of two depressurization vessels operated in parallel. While one is being filled, the other is discharging its load into a mechanism that wets and cools the shale. The shale leaves the retort and is discarded in a water slurry. The residual carbon is not used at present.

Recycle gases carrying the evolved products travel through a *recovery system* that starts with two cyclones to remove dust particles and heavy-oil mist. This operation is followed by electrostatic precipitation. The gases are then compressed, and the recycle gas streams required by the retort are separated. The balance of the gases passes into a refrigerated condenser that separates light oils. The gases are then scrubbed with sodium carbonate in an absorption tower to remove mercaptans and sulfur dioxide. The gases subsequently enter a second tower, where hydrogen sulfide is absorbed by a stream of diethanolamine. The absorbed sulfur is recovered in a Claus unit. The cleaned gases have a high heating value and are suitable for pipelining.

The plant was designed to process 2200 t/d of mined shale and to produce 1000 barrels of oil per day, 17 t/d of sulfur, and 36 500 m^3/d of high-BTU fuel gas. It reached those production levels in 1975 during the demonstration phase, but ithas been operating at somewhat lower throughput in commercial production.

Lurgi Tunnel Kiln. In the Lurgi Tunnel kiln (Fig. 10), the oil shale is retorted in wagonettes moved forward periodically through a tunnel. The heat carrier used is retort gas, which is passed through tubular heaters and then through the shale bed in the wagonettes. The kiln is particularly suitable for very high-grade shales that temporarily become plastic during retorting (e.g., Estonian kukersite shale). Two kilns, each with a throughput capacity of 450 t/d, were installed in the late 1930s for the retorting of oil chalk in Germany, and another four kilns of the same size were erected later for the treatment of Estonian kukersite shale. The oil yield from this class 2 b retorts reaches 95 % of the Fischer assay.

7.2.3. Class 3 (Directly Solids-Heated) Retorts

Class 3 retorts appear to have a high potential for large-scale unit capacities because they can easily be scaled up, produce high oil yields, and

Figure 10. Lurgi tunnel kiln

use fine granular shale that must be rejected in most class 2 retorts.

Lurgi – Ruhrgas Retort. The Lurgi – Ruhrgas (LR) process was used on a commercial scale in the 1960s to carbonize fine-grained coal and to crack naphtha and crude oil to produce olefins. Its great flexibility also makes it suitable for retorting oil shale, tar sands, bituminous rocks, etc. A characteristic feature of the process is that the residue itself is used as a circulating heat carrier, which is reheated by combustion of the remaining organic substance during pneumatic conveying.

As shown in Figure 11, the fine-grained feed is mixed with the hot heat carrier from the collecting bin (b) and instantly heated in the screw mixer (c). The resulting gases and vapors are dedusted in the cyclone (e) and then fed to the cooling and condensing system (f). The mixture of fine-grained residue and heat carrier drops into the surge bin (d) and then flows in a moving bed to the bottom leg of the lift pipe (a). From there, it is lifted by preheated air into the collecting bin (b). On its way, the remaining carbon is burned off the spent shale and the material is reheated. Subsequently, the fine-grained material is separated from the gas and recycled to the mixer (c) to serve as a heat carrier. Surplus material is withdrawn from the system and cooled in a waste-heat recovery system. Flue gas flows through the cyclone (g) and finally through an aftertreatment system (h), (i) to recover its sensible heat and remove the remaining dust before it is discharged to the atmosphere.

This process reaches oil yields of ca. 100 % of the Fischer assay, uses the carbon remaining on the retorting residue to heat the system, produces undiluted retort gas with a calorific value of ca. 38 000 kJ/m^3 (STP), and produces little NO_x because of the low combustion temperature in the lift pipe. The magnesium and calcium carbonates found in numerous oil shales are to a certain

Table 7. Oil shale retorting by the LR process (material balance from a pilot plant in kg/t)

extent converted into oxides during the process. Under the operating conditions prevailing in the lift pipe, the oxides rapidly absorb sulfur dioxide and thus have a self-desulfurizing effect on the process flue gas.

Table 7 summarizes the material balances obtained in a continuous LR pilot plant from different oil shales.

The LR process was developed jointly by Lurgi and Ruhrgas at the beginning of the 1950s to flash-carbonize fine-grained coals. The first technical tests were run in Herten (Germany) in a pilot plant designed for a throughput of 12 t/d. The test program allowed for flash-carbonization of various coals to produce town gas, and for cracking liquid hydrocarbons to obtain olefins, by using sand as the circulating heat carrier. This application of the LR process was thereafter termed *sand cracker*.

Industrial-scale LR plants using oil and/or naphtha as feedstocks were built in Leverkusen, Leuna, Rosario, Chiba, and Lanchow. Commercial scale coal-based LR plants were constructed in Lukavac, Bottrop, and Scunthorpe.

Use of the LR retort for oil shale has been tested in a large number of pilot trials that confirmed the process for this feedstock.

Tosco II Retort. The Tosco II process (Fig. 12, see next page) uses circulating ceramic balls to provide the heat required to heat up and retort fine-grained oil shale. The shale and the hot ceramic balls are mixed in a closed rotary retort. The resulting vapors, the ceramic balls, and the spent shale are discharged from the retort. The heat carrier is then separated from the fine-grained spent shale by screening and is reheated in a furnace fired by retort gases. Because no air is admitted to the rotary retort, the resulting gases are not diluted by nitrogen and have a calorific value of about 38 000 kJ/m^3 (STP). The oil yield reaches ca. 100 % of the Fischer value. A demonstration plant operating between 1970 and 1975 was capable of retorting up to 1000 t/d oil shale.

Galoter Retort. The Galoter process (Fig. 13, see next page), developed in Estonia, combines the characteristics of the Tosco II and Lurgi – Ruhrgas processes. Dried oil shale of < 25-mm particle size is mixed with a heat carrier and fed to a rotary reactor. As in the LR process, hot residue is used as a heat carrier. The oil shale is heated to 520 °C in a rotary kiln retort to pyrolyze the organic substances. Thereafter, the retort gases are cleaned and cooled, and the condensed shale oil is withdrawn. Part of the hot spent shale leaving the combustion zone at ca. 800 °C is mixed with fresh shale and recycled to the retort. The retort gas produced from Baltic shale has a high calorific value of ca. 38 000 kJ/m^3 (STP), and the oil yield reaches 100 % of the Fischer value.

The Galoter process was developed in parallel with the Kiviter process because the fields of application of the two processes complement each other. Oil shale with particles sizes of 25 – 125 mm is retorted by the Kiviter process, whereas the Galoter process is tailored to fine-grained shale up to 25-mm diameter.

A Galoter pilot plant with a capacity of about 500 t/d has been in operation in Estonia since 1964. This pilot plant had operated for 4100 d (11.2 a) by 1979. Over this period 1.76×10^6 t of shale was treated, yielding 235 000 t of commercial oil products and 102×10^6 m^3 of high-energy gas having a combustion heat of ca. 42 000 kJ/m^3 (STP). In 1979 two commercial-size units with a capacity of 3300 t/d each were commissioned in Estonia. The plants were reported to have startup problems in 1981 but appear to have been operational since then.

An Estonian report gives the following process materials balance on 1 t of run-of-mine Baltic shale (in kg/t) yielding 16.6 wt % oil (43 gallons per ton; 180 L/t) by Fischer assay: oil recovery by the Galoter system is 85 – 90 % of Fischer assay. Electrical energy used is 24 kW · h per tonne of wet feed shale.

Chevron STB Retort. The Chevron STB retort is a small-particle retorting process in which retorted shale is burned in a separate combustor and recycled to the retort to supply the process heat requirement. The flow scheme for the core of the process is shown schematically in Figure 14. Fresh-shale preheating facilities and heat-recovery facilities for the flue gas and spent shale are not shown.

The environment in the retort section can best be described as a staged, moving bed of particles, in which a portion of the particles are fluidized. Solids move downward through the retort with an average velocity of 0.6 – 1.5 m/min. Proprietary internals within the retort restrict mixing in the vertical direction and thereby produce "staging" of the solids flow. The "staging" gives an approach to plug flow for the solids and thereby improves the stripping action of the countercurrent gas flow and minimizes the residence time required to assure complete retorting. Locally, conditions within the bed have all the appearances of a fluidized state, although the superficial gas velocity is far below the minimum fluidization velocity of many of the particles.

The retort can be operated with a stripping gas consisting of either recycled product gas, steam, or an inert gas. The superficial gas velocity at the bottom of the retort is 0.3 – 1.5 m/s. The volumetric flow of gas in the retort increases significantly in going from the bottom to the top because of the vapor added by the pyrolysis products.

The combination of thermal shock experienced by fresh shale on entering the retort, the pyrolysis of binding kerogen, and turbulent conditions within the retort cause a certain breakup of the shale. The finest particles are swept overhead from the retort with the product vapors. Most of the elutriated particles are recovered from the vapor stream before condensation of the oil. The recovered particles, collected by primary and secondary devices, contain carbonaceous residue and are therefore burned in the combustor section for recovery of their fuel value.

In the *product recovery section,* product vapors are condensed in stages, which yields several oil fractions and foul water. The initial condensation stage must be capable of handling a certain amount of solids, because the fines removal equipment is never 100 % efficient. Either the noncondensable gases are produced directly or a portion is recycled to the retort for stripping. With very lean shale, some or all of the product gas can be used as a supplementary fuel in the combustor.

The *combustion section* receives coarse retorted shale withdrawn from the bottom of the retort and retorted shale fines removed from the product vapors. Air injected at the bottom of the combustor both transports the shale pneumatically and combusts the carbonaceous residue. The temperature of the solids rises rapidly. At the outlet of the combustor, a solids separator splits the stream once again into fine and coarse fractions. Most of the hot, coarse fraction is recycled to the retort to provide the necessary process heat. Excess coarse shale is sent on to the heat recovery section, from which it is eventually discharged as coarse spent shale. The fine fraction exits the separator with the flue gas. This stream is also sent to the heat recovery section, where it is cooled and separated into a fine spent shale stream and a flue gas stream.

Chevron built and operated a 300-t/d pilot unit in its Salt Lake City refinery (Utah) in the 1980s. The plant has since been dismantled.

7.3. In Situ Processing of Oil Shale

An attractive alternative to the technically proven aboveground retorting processes may be available if attempts at developing economically viable in situ processes turn out to be successful. Large quantities of spent shale would not have to be dumped, nor would areas that had been destroyed by shale mining or dumping have to be reclaimed.

In situ processing of oil shale was practiced on an industrial scale in Sweden during and after World War II. Oil yields reached 60 % of the Fischer value. However, the thermal efficiency, including the electricity required to heat the shale, did not exceed 16 %. On a much smaller scale, oil shale was also processed in situ during World War II in Württemberg (Germany).

In 1965, the U.S. Bureau of Mines began an extensive testing program for the in situ retorting of oil shale in the western United States; the tests had little success. Several in situ projects that were test-operated by private oil companies in the western United States a number of years ago were not successful either.

However, from 1975 onward a *vertical, modified in situ process* tested in the oil shale deposits of the western United States gained more attention, and a number of successful results have already been reported. Such projects were operated by the Occidental Oil Company and Rio Blanco in the Green River formation.

These modified in situ processes require that the oil shale be mined underground to a certain degree. A cavity of $40 \times 40 \times 40\ m^3$, for example, is produced by underground mining, and the oil shale above this cavity is then blasted by explosives to provide a chimney or retort, which may be as much as 150 m high, filled with fractured shale. This loose shale bed can now be retorted in situ. Actually, this is not an in situ process in the narrow sense of the word, because some of the oil shale must be mined and retorted aboveground, and the blasted shale filling the chimney has also been transported, although not a long way.

Horizontal, modified in situ retorting is a variation of the vertical process. Geokinetics has operated a plant in the Green River formation in Utah to exploit a deposit ca. 25-m thick by the horizontal process. This also involves fracturing the shale layer (which must be close to the surface) with explosives and subsequently retorting the deposit horizontally.

In the *Bronco project* proposed in the United States, a 90 kilotonne nuclear explosion was planned in an oil shale formation of great thickness, which should break up the rock and make it suitable for subsequent in situ processing. According to this scheme, a burning wavefront would travel through the fractured rock downward from the top. However, social and environmental factors have prevented this project from being realized.

8. Combustion

Combustion of Pulverized Oil Shale. For ca. 60 years, oil shale has been combusted directly in power stations in Estonia. The Narva power station in the Baltic region, one of the largest thermal power stations in the Soviet Union, burns pulverized oil shale with a relatively high calorific value of ca. 9200 kJ/kg. However, the fact that the oil shale deposits are the only fuel resources in the entire region must not be overlooked.

Direct combustion of pulverized oil shale involves a number of problems resulting from its high ash content. Examples are corrosion and

■ Walls of pipes cooled by circulated water; □ Fire resistant pipe walls

fouling of the heat-transfer surfaces. For this reason, oil shale – although in principle valuable as a fuel – is not of general interest today.

Tests performed by German firms proved that Moroccan oil shale can be used for power generation in pulverized shale-fired boilers if the boiler plant and the auxiliary systems are specifically designed for this fuel. Capital investment would then be ca. 14 % higher than for an oil-fired power station with the same output.

Combustion of Fine Granular Oil Shale. A commercial fluidized-bed combustor for 700-t/d fine granular oil shale is operated by the Rohrbach cement works in Germany [28]. Its main product is shale ash that is used in cement production. Heat released during combustion is used to calcine the high-carbonate shale and to generate steam for electric power production.

The combustion of fine granular (0 – 7 mm) oil shale in circulating fluidized bed (CFB) boilers has attracted attention over the past few years because most of the disadvantages associated with pulverized shale boilers can be avoided with this system. Because the combustion temperature is substantially lower (typically 850 °C), sintering or melting of the ash is avoided; sulfur capture by carbonates contained in the ash or added as limestone is higher; and NO_x formation is lower.

Figure 15 shows the CFB boiler system as developed by Lurgi. The CFB boiler has been widely used for various types of coal, but until now only two small oil shale CFB boilers have been built in Canada (70 MW_{th}) and Israel (41 MW_{th}).

9. Gasification

Industrial-scale gasification of oil shale began in Estonia in 1925, with the use of rotating-grate generators (Pintsch type) to produce not only gas but also ca. 170 kg of oil per tonne of shale. This process is still used in Estonia today.

In the United States, work on oil shale gasification has been continuing with certain interruptions since the 1960s. Laboratory tests at the Institute of Gas Technology (IGT) in Chicago have shown that between 87 and 97 % of the carbon contained in the organic material of Colorado oil shale can be converted to useful fuel gases by a hydrogenating gasification process at

hydrogen pressure up to 3.5 MPa. The laboratory reactor was a traveling-bed device with a diameter of 10 cm and a height of 7.5 m. The test results were encouraging. However, the oil shale had to be ground to very fine particles sizes, and difficulty was encountered in maintaining the specified temperature profiles. The reaction products differed as a function of operating temperature, retention time, and hydrogen partial pressure. The carbon was either completely gasified or reacted to a liquid – gas mixture. If carbon in the organic shale material is to be converted completely into gaseous hydrocarbons, severe reaction conditions, such as a very high pressure and a large hydrogen surplus, are required. At lower temperature, more and more liquid products result. This effect has also been observed during tests to upgrade bitumen from tar sands. The tendency therefore is to put up with a larger percentage of liquid products for economic reasons.

Since 1975, IGT has operated a process plant with throughputs up to 900 kg/h. This plant can handle oil shale with particle sizes up to 25 mm in a batchwise operation [29]. Rather than aiming at complete gasification of the oil shale in a single step, IGT's more recent research has concentrated on separate gasification of the shale oil.

Supported by public funds, Dow Chemical Company has been working since 1977 on projects to produce mainly gas by retorting, gasifying, and burning in situ the black Devonian shale found in Michigan.

10. Properties and Uses of the Products

Shale oil, distillation gas, and shale residue are the main products of an oil shale retorting plant.

Shale Oil. Shale oil may be refined to obtain conventional fuel oils, jet propulsion fuels, diesel oil, naphtha, and gasoline. Once the distillation gases have been removed, shale oil is obtained as a dark, viscous liquid with a high content of sulfur, nitrogen, and unsaturated compounds. Shale oil solidifies in the temperature range of 15 – 25 °C because of its high pour point.

Most important among the various *shale oil upgrading processes* are

1) *Coking* This method cannot be recommended, because considerable losses occur due to the production of low-grade coke.
2) *Hydrogenation or Hydrovisbreaking* By catalytic hydrogenation under pressure, shale oils can be converted to motor fuels with low sulfur and nitrogen content, yielding elemental sulfur and ammonia as byproducts.

Typical properties of various crude shale oils are listed in Table 8.

Distillation Gas. After elimination of condensable oils and vapors, the distillation gas from an oil shale retort consists mainly of carbon monoxide, carbon dioxide, hydrogen, methane, hydrogen sulfide, and nitrogen. It also contains liquefied petroleum gas and some naphtha vapors, which may be recovered partly by means of wash oil, activated carbon, or cryogenic separation. Depending on the retorting process used, the calorific value of the distillation gas (without gas naphtha) varies between 5.4 and 39.8 MJ/m^3 (STP). It may serve as fuel gas for industrial purposes, or if itcontains little nitrogen, it may be used in a reformer to produce hydrogen for refining. Alternatively, the product may be shift-converted, cleaned, and methanated catalytically to upgrade it to substitute natural gas.

Shale Residue. The shale residue is normally an undesirable byproduct and must be returned to the pit or dumped in a landfill area. Depending on the retorting process and type of oil shale, the residue still contains 1 – 15 % combustible matter. Aftercombustion of shale residue may therefore be of interest. Residues containing high percentages of calcium oxide may have the properties of hydraulic binders and could be used as additives in the cement industry.

11. Outlook

Although numerous oil shale deposits exist on all continents, the oil shale industry can be expected to develop further only if certain economic conditions are fulfilled. Special events such as an oil embargo or problems of national security may speed up developments, especially if they lead governments to subsidize the oil shale industry.

Table 8. Shale oil analyses

Shale origin		Green River (United States)		Schandelah (Germany)	Timahdit (Morocco)	Alexinac (Yugoslavia)

1. Introduction

The eye is an external organ, and is susceptible to injury, infection, and irritation, as well as to organic and functional disorders. The products and preparations for ophthalmic use therefore comprise a broad category and include medications, diagnostic agents, and medical device formulations.

Over-the-counter and prescription medications are used to treat chronic ailments (e.g., glaucoma, blepharitis, and dry eye), as well as temporary conditions (e.g., infections, allergic reactions, and injuries).

Ocular diagnostic agents are a specialized group of drugs and dyes utilized primarily for ocular examination and the identification of potential disease conditions.

Medical device products are used for the hydration, wetting, cleaning, and disinfection of contact lenses.

[Top of Page]

2. Anesthetics

Topical anesthetics diminish sensory nerve impulse generation and conduction locally, and are used to anesthetize the ocular surface during short corneal or conjunctival procedures (e.g., tonometry, removal of sutures or foreign bodies) [1-4]. Proxymetacaine (0.5 %), oxybuprocaine (0.4 %), or tetracaine (0.25 – 1.0 %) solutions are commonly used [1]; proxymetacaine is particularly useful [4]. These agents provide rapid onset of local anesthesia of relatively short duration (e.g., one or two drops of a 0.5 % proxymetacaine solution take effect within 30 s with anesthesia lasting about 15 min). Cocaine exhibits significant corneal epithelial toxicity and is now rarely used; however, it may still be employed for debridement of the corneal epithelium, as in herpetic epithelial keratitis [3], [4]. Topical application of combinations of local anesthetics does not provide additive effects but increases the risk of side effects [2].

Regional anesthetics are employed in ophthalmic surgical procedures. They are administered by injection for infiltration anesthesia or for regional nerve block (facial or retrobulbar) anesthesia [1-3]. Onset of action is typically 3 – 11 min, and anesthesia may last from 30 – 45 min (procaine) up to 300 – 600 min (etidocaine) or longer (480 – 720 min for bupivacaine with epinephrine) [2]. Combination of injectable anesthetics with vasoconstrictors such as epinephrine decreases the rate of systemic absorption and prolongs the duration of anesthesia.

Most of the anesthetics listed in Sections Antibacterial Agents and Antifungal Agents are described in detail elsewhere, see ⟶ .

2.1. Topical Anesthetics

Cocaine hydrochloride [53-21-4], $C_{17}H_{21}NO_4 \cdot HCl$, M_r 339.8. Cocaine is not commercially available as a solution for clinical use.

Proxymetacaine hydrochloride [5875-06-9], 2-diethylaminoethyl 3-amino-4-propoxybenzoate monohydrochloride, proparacaine hydrochloride, $C_{16}H_{26}N_2O_3 \cdot HCl$, M_r 330.9.

Trade names: Ak-taine (Akorn); Alcaine (Alcon); Kainair (Pharmafair); Keracaine, Kerakain (Chibret); Ocu-caine (Ocumed); Ophthaine (Squibb); Ophthetic (Allergan).

Tetracaine hydrochloride [136-47-0], 2-dimethylaminoethyl 4-butylaminobenzoate monohydrochloride, $C_{15}H_{24}N_2O_2 \cdot HCl$, M_r 300.8.

Trade names: Minims Amethocaine Hydrochloride (Smith & Nephew), Pontocaine (Winthrop).

Oxybuprocaine hydrochloride [5987-82-6], 2-diethylaminoethyl 4-amino-3-butoxybenzoate monohydrochloride, benoxinate hydrochloride, $C_{17}H_{28}N_2O_3 \cdot HCl$, M_r 344.9.

Trade names: Alcon Opulets Benoxinate (Alcon); Cebesine (Chauvin-Blanche); Conjuncain (Mann); Minims Benoxinate Hydrochloride, Minims Oxybuprocaine Hydrochloride (Smith & Nephew); Novesin (Dispersa); Novesina (Sandoz); Novesine (Chibret, Wander); Oftalmocaina, Oxibuprokain Minims (Smith & Nephew); Poen Caina, Prescaina (Llorens).

Oxybuprocaine hydrochloride (0.4 %) is available in combination with sodium fluorescein (0.25 %) under the trade name Fluress (Sola/Barnes – Hind) for applanation tonometry.

2.2. Regional Anesthetics

Bupivacaine hydrochloride [18010-40-7] (monohydrate [14252-80-3]), 1-butyl-*N*-(2,6-dimethylphenyl)-2-piperidinecarboxamide monohydrochloride monohydrate, $C_{18}H_{28}N_2O \cdot HCl \cdot H_2O$, M_r 342.9.

Etidocaine hydrochloride [36637-19-1], *N*-(2,6-dimethylphenyl)-2-(ethylpropylamino)butanamide monohydrochloride, $C_{17}H_{28}N_2O \cdot HCl$, M_r 312.9.

Hexylcaine hydrochloride [532-76-3], 2-cyclohexylamino-1-methylethyl benzoate monohydrochloride, $C_{16}H_{23}NO_2 \cdot HCl$, M_r 297.8.

Lidocaine hydrochloride [73-78-9] (anhydrous), monohydrate [6108-05-0], 2-diethyl-aminoaceto-*N*-(2,6-dimethylphenyl)acetamide monohydrochloride monohydrate, $C_{14}H_{22}N_2O \cdot HCl \cdot H_2O$, M_r 288.8.

Mepivacaine hydrochloride [1722-62-9], *N*-(2,6-dimethylphenyl)-1-methyl-2-piperidinecar-boxamide hydrochloride, $C_{15}H_{22}N_2O \cdot HCl$, M_r 282.8.

Prilocaine hydrochloride [1786-81-8], *N*-(2-methylphenyl)-2-(propylamino)propanamide hydrochloride, $C_{13}H_{20}N_2O \cdot HCl$, M_r 256.8.

Procaine hydrochloride [51-05-8], 2-diethylaminoethyl 4-aminobenzoate hydrochloride, $C_{13}H_{20}N_2O_2 \cdot HCl$, M_r 272.8.

Tetracaine hydrochloride (see Section Topical Anesthetics).

[Top of Page]

3. Antimicrobial Agents

3.1. Antibacterial Agents

Successful therapy for bacterial infection with antibiotics relies upon five considerations:

1. Appropriate indications for use
2. Isolation and identification of the infective agent
3. Efficacy of the antibiotic for the infective agent
4. Adequate levels of the antibiotic at the site of infection
5. Low toxicity of the antibiotic for the host [5]

Antibiotics act upon bacteria through a variety of mechanisms. The penicillins, cephalosporins, vancomycin, and bacitracin inhibit development of the bacterial cell wall. Tetracycline, erythromycin, clindamycin, chloramphenicol, and the aminoglycosides inhibit protein synthesis.

3.1.1. *Sulfonamides*

See also ⟶ Chemotherapeutics – Sulfa Drugs.

Although the use of sulfonamides for the treatment of major bacterial infections has been largely supplanted by antibiotics, they are still prescribed for the topical treatment of minor ocular infections. They exhibit broad-spectrum bacteriostatic activity against many gram-positive and gram-negative organisms, and are useful against the protozoa *Toxoplasma gondii* and *Plasmodium falciparum*. Some strains of *Pseudomonas, Chlamydia*, and *Actinomyces* are also sensitive to these drugs. A major disadvantage is the frequent occurrence of cross-resistant microorganisms. Many side effects have been reported following the topical administration of sulfonamides. These drugs are contraindicated for the treatment of keratoconjunctivis sicca or penetrating corneal wounds. Sulfacetamide sodium is the most widely used sulfonamide at a concentration of 10 %, or in combination with the steroid prednisolone acetate (0.2 – 0.5 %).

The sulfonamides are antimetabolites. Their structural similarities to 4-aminobenzoic acid allow them to act as competitive inhibitors in the folic acid biosynthetic pathway.

Sulfacetamide sodium [144-80-9], *N*-[(4-aminophenyl)sulfonyl]acetamide, $C_8H_{11}N_2NaO_3S$, M_r 238, *mp* 182 – 184 °C, is incorrectly called sulfacetimide. For synthesis, see [6].

Trade names: Ak-Cide, Ak-Sulf (Akorn); Bleph-10, Blephamide Liquifilm/S.O.P. (Allergan); Cetamide Ointment, Cetrapred Ointment (Alcon); FML-S (Allergan); Isopto Cetmide Solution (Alcon); Metimyd Ophthalmic Solution/Ointment — Sterile (Schering); Ocu-Lone-C Sterile Ophthalmic Ointment/Suspension (Ocumed); Predsulfair Ointment/Suspension (Pharmafair); Sodium Sulamyd Ophthalmic Ointment 10 %, Sodium Sulamyd Ophthalmic Suspension 10 % (30 %) — Sterile (Schering); Sulf-10 Dropperettes 10 %/Ophthalmic Solution 10 % (IOLAB); Sulfair (Pharmafair); Sulphrin (Bausch & Lomb); Sulpred Suspension (Pharmafair); Sulten-10 (Bausch & Lomb); Vasocidin Ointment/Solution, Vasosulf (IOLAB).

Sulfadiazine [68-35-9] (sodium [547-32-0], silver [22199-08-2]), 4-amino-*N*-2-pyrimidinylbenzenesulfonamide, $C_{10}H_{10}N_4O_2S$, M_r 250.3, *mp* 252 – 256 °C. For synthesis, see [7].

Sulfamerazine sodium [127-58-2], 4-amino-*N*-(4-methyl-2-pyrimidinyl)benzenesulfonamide sodium salt, $C_{11}H_{11}N_4NaO_2S$, M_r 286.3. For synthesis, see [7]. Sulfamerazine sodium is a short-acting sulfonamide with action similar to that of sulfamethoxazole. It is usually administered with other sulfonamides.

Sulfamethizole [144-82-1], 4-amino-*N*-(5-methyl-1,3,4-thiadiazol-2-yl)benzenesulfonamide,$C_9H_{10}N_4O_2S_2$, M_r 270.3, *mp* 208 °C. For synthesis, see [8].

Sulfisoxazole diolamine [4299-60-9], 4-amino-*N*-(3,4-dimethyl-5-isoxazolyl)benzenesulfonamide diethanolamine, M_r 372.4. For synthesis, see [9].

Trade names: Ganstrin Ophthalmic Ointment/Solution, Suladrin, Sulfium (Roche).

3.1.2. β-*Lactam Antibiotics*

3.1.2.1. *Penicillins*

Penicillins are effective antimicrobials, although they have two drawbacks: (1) microbial resistance is relatively common, and (2) penicillins may be antigenic; anaphylactic shock is therefore a concern when they are administered systemically. See also ⟶ Antibiotics – Semisynthetic Penicillins.

Ampicillin [69-53-4], (sodium derivative [69-52-3], trihydrate [7177-48-2]), $C_{16}H_{19}N_3O_4S$, M_r 349.42, *mp* 202 °C (decomp.). Ampicillin is a semisynthetic derivative of penicillin. For synthesis, see [10]. See also ⟶ Antibiotics.

Methicillin sodium [132-92-3], $C_{17}H_{19}N_2NaO_6S$, M_r 402.42, *mp* 196 – 197 °C. Methicillin sodium is a semisynthetic antibiotic related to penicillin. For synthesis, see [11]. See also ⟶ Antibiotics.

3.1.2.2. *Cephalosporins*

The cephalosporins originated from a mold of the genus *Cephalosporium*. Although cephalosporins do not usually cause an allergic reaction in patients sensitized to penicillin, allergy to cephalosporins can also develop. The cephalosporins are not inactivated by penicillin-resistant bacteria and have a broader spectrum of activity than penicillin. See also ⟶ Antibiotics – Natural Cephalosporins ⟶ Antibiotics – Semisynthetic Cephalosporins ⟶ Antibiotics – Cephamycins.

Carbenicillin [4697-36-3] (disodium derivative [4800-94-6], indanyl sodium derivative [26605-69-6], phenyl sodium derivative [21649-57-0]), $C_{17}H_{18}N_2O_6S$, M_r 378.42. For synthesis, see [12]. See also ⟶ Antibiotics ⟶ Antibiotics ⟶ Antibiotics.

Cefazolin [25953-19-9] (sodium salt [27164-46-1]), $C_{14}H_{14}N_8O_4S_3$, M_r 454.50, *mp* 198 – 200 °C. For synthesis, see [13]. For structure, see ⟶ Antibiotics – Semisynthetic Cephalosporins.

Cephalothin [153-61-7] (cephalothin sodium [58-71-9]), $C_{16}H_{15}N_2NaO_6S_2$, M_r 418, *mp* 160 °C. Cephalothin is a semisynthetic cephalosporin antibiotic. For synthesis, see [14]. For structure, see ⟶ Antibiotics – Semisynthetic Cephalosporins.

3.1.3. *Tetracycline Antibiotics*

Tetracyclines reversibly block protein synthesis by specifically binding to the bacterial ribosome. Tetracycline and chloramphenicol were the first broad-spectrum antimicrobials discovered. The tetracycline antibiotics listed below are described in detail elsewhere; see ⟶ Antibiotics – Tetracyclines.

Chlortetracycline hydrochloride [64-72-2] (chlortetracycline [57-62-5]), $C_{22}H_{24}Cl_2N_2O_8$, M_r 493.9. Chlortetracycline is isolated from *Streptomyces aureofaciens* [15]. See also ⟶ Antibiotics

Trade name: Aureomycin Ophthalmic (IOLAB).

Oxytetracycline [79-57-2] (hydrochloride [2058-46-0]), $C_{22}H_{24}N_2O_9$, M_r 460.44, is an antibiotic isolated from the fermentation of *Streptomyces rimosus* [16]. See also ⟶ Antibiotics

Trade name: Terramycin (5 mg/mL) with Polymyxin B Ointment (10 000 U/mL) (Roerig).

Tetracycline [60-54-8] (hydrochloride [64-75-5], phosphate complex [1336-20-5]), $C_{22}H_{24}N_2O_8$, M_r 444.43, is an antibiotic produced by *Streptomyces* spp. [17], [18]. See also ⟶ Antibiotics

Trade names: Achromycin and Achromycin Ophthalmic Ointment 1 % (IOLAB).

3.1.4. *Aminoglycoside Antibiotics*

The aminoglycoside antibiotics exhibit broad-spectrum antimicrobial activity, particularly against gram-negative organisms (⟶ Antibiotics – Aminoglycosides). They inhibit protein synthesis and decrease translational efficiency through interaction with the 30 S subunit of bacterial ribosomes. Cross resistance exists among the aminoglycosides.

Aminoglycosides are generally administered topically because systemic adsorption may produce oto- and nephrotoxicity. Aminoglycosides and β-lactam antibiotics are incompatible in the same formulation. Aminoglycosides are not effective under acid conditions, in high salt concentrations, or against intracellular bacteria.

Framycetin sulfate [4146-30-9], [28002-70-2], the sulfate of neomycin B, $C_{23}H_{46}N_6O_{13} \cdot 3\ H_2SO_4$, M_r 908.9. Neomycin B is isolated from the mixture of neomycins A, B, and C produced by *Streptomyces fradiae*; see also ⟶ Antibiotics [19]. Framycetin sulfate has broad-spectrum activity similar to that of neomycin but is more efficacious against *Pseudomonas* spp. Unlike most other aminoglycosides, framycetin sulfate can be administered by subconjunctival injection; however, because of its high degree of systemic absorption, extreme caution must be employed to avoid toxicity.

Trade names: Framygen (Fisons), Soframycin (Roussel), with 0.5 % hydrocortisone acetate in Framycort (Fisons), with 0.05 % dexamethasone and 0.005 % gramicidin in Sofradex (Roussel).

Gentamicin sulfate [1405-41-0] (gentamycin [1403-66-3]) is a complex mixture of the sulfates of gentamicin C_1, C_{1a}, and C_2. This complex is produced by fermentation of *Micromonospora purpurea* [20]; see also ⟶ Antibiotics. Gentamicin sulfate is used as a drop, ointment, or buffered preserved solution, generally at a concentration of 0.3 %.

Trade names: Alcomicin (Alcon); Cidomycin (Roussel); Garamycin (Kirby-Warrick); Garamycin Ophthalmic Ointment/Solution — Sterile (Schering); Genopyic (Allergan); Gentacidin (CooperVision); Gentafair (Pharmafair); Genticina (Antibioticos); Genoptic Liquifilm Sterile Ophthalmic Solution (Allergan); Genoptic S.O.P. Sterile Ophthalmic Ointment (Allergan); Gentafair Cream and Ointment/Solution (Pharmafair); Gentak Ointment and Solution (Akorn); Genticidin Ointment/Solution (IOLAB); Gentrasul Ointment/Solution (Bausch & Lomb); Minims Centamicin Sulfate (Smith & Nephew); Ocu-Mycin Sterile Ophthalmic Ointment/Solution (Ocumed); Pred-G Liquifilm Sterile Ophthalmic Suspension (Allergan); Pred-G S.O.P. Sterile Ophthalmic Ointment (Allergan).

Micronomicin sulfate (micronomicin [52093-21-7]), $(C_{20}H_{41}N_5O_7)_2 \cdot 5\ H_2SO_4$, M_r 1417.5, *mp* 260 °C. This gentamicin C complex antibiotic is produced by *Micromonospora sagamiensis* var. *nonreducans* [21].

Trade names: Sagamicin (Kyowa), Santemycin (Santen).

Neomycin [1404-04-2] is an antibiotic complex made up of neomycins A, B, and C from *Streptomyces fradiae* [22-24]. See also ⟶ Antibiotics.

Trade names: Ak-Spore (H.C.) Ointment/Solution, Ak-Trol Ointment & Suspension (Akorn); Cortisporin Ophthalmic Ointment/Suspension (Burroughs Wellcome); Dexacidin Ointment/Suspension (IOLAB); Dexasporin Ointment/Suspension (Pharmafair); Infectrol Ointment/Suspension (Bausch & Lomb); Maxitrol Ophthalmic Ointment/Suspension (Alcon); NeoDecadron Sterile Ophthalmic Ointment (Merck Sharp & Dohme); Neo Dexair Ophthalmic Solution (Pharmafair); Neosporin Ophthalmic Ointment/Solution (Burroughs Wellcome); Neotricin Ointment/Solution (Bausch & Lomb); Ocu-Cort Sterile Ophthalmic Ointment, Ocu-Spor-B Sterile Ophthalmic Ointment, Ocu-Spor-G Sterile Ophthalmic Solution (Ocumed); Ocutricin HC Ointment/Suspension, Ocutricin Ointment/Solution (Pharmafair); Ocu-Trol Sterile Ophthalmic Ointment/Suspension (Ocumed); Poly-Pred Liquifilm (Allergan).

Sisomicin [32385-11-8] (sulfate [53179-09-2]), $C_{19}H_{37}N_5O_7$, M_r 447.6, monohydrate from ethanol, *mp* 198 – 201 °C. Sisomicin is an antibiotic produced by *Micromonospora inyoesis* [25]. It is usually administered systemically and not commonly used as an ophthalmic antibiotic. See also ⟶ Antibiotics – Sisomicin.

Streptomycin sulfate [3810-74-0] (streptomycin [57-92-1]), $C_{42}H_{84}N_{14}O_{36}S_3$, M_r 1457.40. Streptomycin is produced by *Streptomyces griseus* [26]; see also ⟶ Antibiotics. Corneal penetration of streptomycin is poor but can be greatly enhanced by iontophoresis.

Tobramycin [32986-56-4] (sulfate [79645-27-5]), $C_{18}H_{37}N_5O_9$, M_r 467.5. Tobramycin is produced by *Streptomyces tenebrarius* [27]. See also ⟶ Antibiotics. Tobramycin has a broad spectrum of activity similar to that of gentamicin. Cross resistance of tobramycin and gentamicin has been observed. Tobramycin is four times more effective against *Pseudomonas aeruginosa*, and less effective against *Serratia*, than gentamicin. Unlike other aminoglycosides, tobramycin is ineffective against mycobacteria.

Trade names: TobraDex Ophthalmic Suspension and Ointment, TobraLex, Tobral, Tobramaxin, Tobrex (Alcon); Tobra-Gobens (Normon); Tobra-Laf (Andalucia).

3.1.5. *Polypeptide Antibiotics*

Bacitracin [1405-87-4], bacitracin A (major component): $C_{66}H_{103}N_{17}O_{16}S$, M_r 1422.71. Commercial bacitracin is a mixture of at least nine bacitracins produced by *Bacillus subtilis* and *B. licheniformis* [28], [29]; see ⟶ Antibiotics. It is available singly only as an ointment (500 mg/g) and in combination with other antimicrobials (see Table 1).

Table 1. Combination antibiotic solutions and ointments *

Product	Polymyxin B sulfate, units/g	Neomycin, mg/g	Bacitracin, units/g	Oxytetracycline, mg/g	Gramicidin, mg/mL	Company
Neotal Ophthalmic Ointment	5000	5	400			Hauck
Terramycin with Polymyxin B Ointment	10000			5		Roerig
Ak-Poly-Bac Ointment	10000		500			Akorn
Polysporin Ointment	10000		500			Burroughs Wellcome
Neomycin Sulfate–Polymycin B Sulfate–Gramicidin Solution	10000*	1.75**			0.025	Rugby
Ak-Spore Solution	10000*	1.75**			0.025	Akorn
Neocidin Solution	10000*	1.75**			0.025	Major
Neosporin Ophthalmic Solution	10000*	1.75**			0.025	Burroughs Wellcome
Neotricin Opthalmic Solution	10000*	1.75**			0.025	Bausch & Lomb
Statrol Ointment	10000	3.5				Alcon
Ak-Spore Ointment	10000	3.5	400			Akorn
Neosporin Ophthalmic Ointment	10000	3.5	400			Burroughs Wellcome
Neotricin Ointment	10000	3.5	400			Bausch & Lomb
Mycitracin Ophthalmic Ointment	10000	3.5	500			Upjohn
Statrol Solution	16250*	3.5**				Alcon

* Units/mL. ** mg/mL.

Trade names: Ak-Poly-Bac Ointment, Ak-Spore (H.C.) Ointment (Akorn); Bacitracin Ophthalmic Ointment — Sterile (Pharmafair); Cortisporin Ophthalmic Ointment Sterile, Neosporin Ophthalmic Ointment Sterile (Burroughs Wellcome); Neotricin Ointment/Solution (Bausch & Lomb); Ocumycin (HC) Ointment (Pharmafair); Polysporin Ophthalmic Ointment Sterile (Burroughs Wellcome).

Colistimethate sodium [8068-28-8], $C_{58}H_{105}N_{16}Na_5O_{28}S_5$, M_r 1749.8. Colistimethate sodium is an injectable form of colistin, a cyclopolypeptide produced by *Bacillus colistinus* [30]. See also ⟶ Antibiotics.

Trade name: Coly-Mycin M (Parke-Davis).

Polymyxin B sulfate [1405-20-5] is a mixture of polymyxins B_1 and B_2 produced by *Bacillus polymyxa* [31], [32]. See also ⟶ Antibiotics. Polymyxins are cyclic polypeptides that are similar to detergents in having basic groups with a fatty acid side chain. They exert their antimicrobial effect by solubilizing the cell membrane. Polymyxin B sulfate is available as a sterile powder for reconstitution or in combination with other antimicrobials (see Table 1).

Trade names: Ak-Poly-Bac Ointment, Ak-Spore (H.C.) Ointment/Suspension, Ak-Trol Ointment & Suspension (Akorn); Cortisporin Ophthalmic Ointment/Suspension (Burroughs Wellcome); Dexacidin Ointment/Suspension (IOLAB); Dexasporin Ointment/Suspension (Pharmafair); Infectrol Ointment/Suspension (Bausch & Lomb); Maxitrol Ophthalmic Ointment/Suspension (Alcon); Neosporin Opthalmic Ointment/Ophthalmic Solution Sterile (Burroughs Wellcome); Neotricin Ointment/Solution (Bausch & Lomb); Ocu-Cort Sterile Ophthalmic Ointment (Ocumed); Ocumycin Ointment (Pharmafair); Ocu-Spor-B Sterile Ophthalmic Ointment, Ocu-Spor-G Sterile Ophthalmic Solution (Ocumed); Ocutricin HC Ointment/Suspension, Ocutricin Ointment/Solution (Pharmafair); Ocu-Trol Sterile Ophthalmic Ointment/Suspension (Ocumed); Opthocort (Parke-Davis); Polymyxin B Sulfate Sterile Ophthalmic (Pfizer); Poly-Pred Liquifilm (Allergan); Polysporin Ophthalmic Ointment Sterile (Burroughs Wellcome).

3.1.6. *Miscellaneous Antimicrobial Agents*

Chloramphenicol [56-75-7], $C_{11}H_{12}Cl_2N_2O_5$, M_r 323.1, *mp* 150.5 – 151.5 °C, is a broadspectrum antibiotic produced by *Streptomyces venezuelae* [33-35]. Chloramphenicol reversibly blocks the bacterial ribosome, inhibiting protein synthesis. See also ⟶ Antibiotics.

Trade names: Ak-Chlor Sterile Ophthalmic Ointment/Solution (Akorn); Chlorofair Ointment/Solution (Pharmafair); Chloromycetin Ophthalmic Ointment/Solution/Powder, Hydrocortisone Ophthalmic Solution (Parke-Davis); Chloroptic S.O.P., Chloroptic Sterile Ophthalmic Solution (Allergan); Ocu-Chlor Sterile Opthalmic Ointment/Solution (Ocumed); Opthochlor Ophthalmic Solution (Parke-Davis).

Clindamycin [18323-44-9] (palmitate hydrochloride [25507-04-4], hydrochloride monohydrate [58207-19-5]), $C_{18}H_{33}ClN_2O_5S$, M_r 424.98, is a semisynthetic antibiotic prepared from lincomycin [36]. See also ⟶ Antibiotics.

Trade name: Cleocin Phosphate (Upjohn).

Erythromycin [114-07-8], $C_{37}H_{67}NO_{13}$, M_r 733.9, *mp* 135 – 140 °C, resolidifies with second *mp* 190 – 193 °C. Erythromycin is produced by *Streptomyces erythreus* [37] and is a mixture of erythromycin A, B, and C, with A predominant. It is the most widely used of the macrolide antibiotics and exerts its effect at the level of protein synthesis by reversibly inhibiting the bacterial ribosome. See also ⟶ Antibiotics – 14-Membered Ring Macrolides ⟶ Antibiotics.

Trade names: Ak-Mycin Ointment (Akorn), Erythromycin Ophthalmic Ointment (Pharmafair), Ilotycin (Dista).

Lincomycin [154-21-2], $C_{18}H_{34}N_2O_6S$, M_r 406.6, is an antibiotic produced by *Streptomyces lincolnensis* var. *lincolnensis* [38], [39]. Lincomycin reversibly inhibits the bacterial ribosome. See also ⟶ Antibiotics.

Trade name: Lincocin (Upjohn).

Ofloxacin [82419-36-1], $C_{18}H_{20}FN_3O_4$, M_r 361.4, *mp* 250 – 257 °C, is a broad-spectrum, fluorinated quinoline antibacterial. See also ⟶ . For synthesis, see [40].

Silver nitrate [7761-88-8], $AgNO_3$, M_r 169.9, *mp* 212 °C, is used to treat the eyes of newborns. Caution should be used with repeated applications because cauterization of the cornea and blindness may result. Silver nitrate is incompatible with sulfacetamide preparations.

Trade name: Silver Nitrate (Lilly).

Vancomycin [1404-90-6] (hydrochloride [1404-93-9]), $C_{66}H_{75}Cl_2N_9O_{24}$, M_r 1449.2. Vancomycin is an amphoteric glycopeptide produced by *Streptomyces orientalis* [41]. It inhibits cell wall synthesis. See also ⟶ Antibiotics.

Trade names: Vancocin (Lilly), Vancoled (Lederle), Vancor (Adria).

3.2. Antifungal Agents

For general information see ⟶ Antimycotics.

Ocular fungal infection is a rare disease but is increasing in occurrence [42-44]. Commensal fungi commonly present in the eye include *Aspergillus*, *Penicillium*, *Candida*, *Fusarium*, and *Rhodotorula*. These may become opportunistic pathogens if the eye's defenses are compromised by physical trauma or an underlying disease such as diabetes.

Although natamycin is the only antifungal agent currently available commercially in the United States as a topical ophthalmic formulation, other antifungal drugs (including polyenes and imidazoles) have been used topically in dilute solution or suspension [45].

The *polyene antimycotics* (amphotericin B, nystatin, natamycin) are insoluble in water and unstable in oxygen, light, water, heat, and at extreme pH. Their biological specificity for yeast relies on preferential binding to yeast membranes via ergosterol over their affinity for cholesterol, the primary sterol in mammalian cell membranes. Cell death is induced by increasing the permeability of the fungal membrane, allowing depletion of intracellular components.

The *imidazoles* (miconazole and ketoconazoles) have a broad antifungal and antimicrobial spectrum, with significantly less toxicity than the polyenes. Antifungal effects may result from the inhibition of estergol synthesis, leading to cell membrane permeability. Miconazole physically disrupts the membrane, leading to cell lysis. High concentrations of miconazole also increase intracellular concentrations of hydrogen peroxide, presumably through inhibition of cytochrome C peroxidase.

Flucytosine is a widely used *pyrimidine antimycotic*.

Amphotericin B [1397-89-3], $C_{47}H_{73}NO_{17}$, M_r 924.1, is a polyene antibiotic produced by *Streptomyces nodosus* [46]. Amphotericin can be administered parenterally for systemic mycosis. Topical administeration of 0.1 and 0.25 % has been effective for the treatment of keratomycoses. See also ⟶ Antimycotics – Amphotericin B.

Trade name: Fungizone (Squibb).

Nystatin [1400-61-9] is a polyene antifungal antibiotic complex containing three active components (A_1, A_2, and A_3) produced by several *Streptomyces* spp.[47]. See also ⟶ Antimycotics – Nystatin A1. Nystatin is effective in topical application for ocular infection.

Trade names: Mycostatin (Squibb), Nilstat (Lederle), Nystex (Savage), O-V Statin (Squibb).

Natamycin [7681-93-8], $C_{33}H_{47}NO_{13}$, M_r 665.75, *mp* 280 – 300 °C (decomp.), is a polyene antibiotic produced by *Streptomyces natalensis* and *S. chattanoogensis* [48]. See also ⟶ Antimycotics – Natamycin (Pimaricin). Natamycin is the least toxic, least irritating, and most stable polyene. It is only useful, however, for the treatment of superficial keratomycosis because it penetrates tissue poorly.

Trade name: Natacyn (Alcon).

Miconazole [22916-47-8] (nitrate [22832-87-7]), $C_{18}H_{14}Cl_4N_2O$, M_r 416.12. See also ⟶ Antimycotics – Miconazole. For synthesis, see [49].

Trade names: Micatin, Monistat-Derm (Ortho).

Ketoconazole [65277-42-1], $C_{26}H_{28}Cl_2N_4O_4$, M_r 531.44, *mp* 146 °C, is an orally active, broad-spectrum antimycotic. See also ⟶ Antimycotics – Ketoconazole. For synthesis, see [50].

Trade name: Nizoral (Janssen).

Flucytosine [2022-85-7], 5-fluorocytosine, $C_4H_4FN_3O$, M_r 129.1, *mp* 295 – 297 °C (decomp.). For synthesis, see [51]. Flucytosine, a fluorinated pyrimidine, is metabolized to either 5-fluorouracil, an inhibitor of RNA synthesis, or 5-fluoro-2′-deoxyuridylic acid, a potent inhibitor of DNA synthesis. Flucytosine has a limited spectrum of activity but is effective in topical application against external infections. It exhibits poor ocular penetration but can be administered orally. See also ⟶ Antimycotics – Flucytosine.

Trade name : Ancobon (Hoffmann – La Roche).

3.3. Antiprotozoal Agents

Broline [496-00-4], 4,4′-(trimethylenedioxy)bis(3-bromobenzamidine), $C_{21}H_{30}Br_2N_4O_{10}S_2$, M_r 722.4, *mp* 226 °C, is used to treat *Acanthamoeba* keratitis infections [52]. For synthesis, see [53].

Trade names: Brolene Eye Drops (Bausch & Lomb); Broline Ointment, Brulidene (May & Baker).

Sulfadiazine [68-35-9] (silver salt [22199-08-2]), 4-amino-*N*-2-pyrimidinylbenzenesulfonamide, $C_{10}H_{10}N_4O_2S$, M_r 250.3, *mp* 252 – 256 °C. For synthesis, see [7]. See also ⟶ . This compound is used to treat toxoplasmic retinochoroiditis in triple sulfonamide mixtures with sulfamerazine and sulfamethazine.

Trade names: Coco-Diazine (Lilly), Eskadiazine (SKF).

Antibiotic – Corticosteroid Preparations. A variety of ophthalmic antibiotic – corticosteroid combination preparations are available for treating protozoal infections. Ophthalmic applications of corticosteroids and corticosteroid – antibiotic combination preparations are discussed in Section Corticosteroids.

3.4. Antiviral Agents

Currently marketed antivirals are available only as topical applications for the treatment of infection with the herpes simplex virus (HSV). These agents inhibit viral replication at the level of DNA synthesis. The prophylactic use of antivirals may reduce the frequency of viral latency [54]. The use of high dosages does not rid the host of latent virus but may reduce the frequency of recurrences during therapy [55].

Acyclovir [59277-89-3], $C_8H_{11}N_5O_3$, M_r 225.2, *mp* 256.5 – 257 °C, is an orally active acyclic nucleoside used against HSV. It is also used as a 3 % ointment in HSV infections of the epithelium. For synthesis, see [56]. See also ⟶ .

Trade name: Zovirax (Burroughs Wellcome).

Idoxuridine [54-42-2], 2′-deoxy-5-iodouridine, $C_9H_{11}IN_2O_5$, M_r 354.1. Idoxuridine is a functional analogue of the nucleoside thymidine; see ⟶ . Incorporation into DNA results in death of the viral particle through DNA base-pair mismatches and mutation. The toxicity of the substance is attributable to its incorporation into the host cell DNA. This agent is best used topically on a superficial lesion and is available as a 0.1 % solution or a 0.5 % ointment. For synthesis, see [57].

Trade names: Herpex (Allergan); Stoxil Ointment, Stoxil Solution (SKF).

Trifluridine [70-00-8], 2′-deoxy-5-(trifluoromethyl)uridine, $C_{10}H_{11}F_3N_2O_5$, M_r 296.2, *mp* 186 – 189 °C. Trifluridine is a thymidine analogue but unlike idoxuridine is rapidly metabolized and thus less toxic. Trifluridine is effective against HSV [58] and, in addition, is compatible with corticosteroids [59]. See also ⟶ . Trifluridine is generally available as a 1 % solution or a 3 % ointment. For synthesis, see [60].

Trade names: TFT-Ophtiole (Mann), TFT Eye Ointment (Mann), Viroptic (Burroughs Wellcome).

Vidarabine (anhydrous [5536-17-4], monohydrate [24356-66-9]), $C_{10}H_{13}N_5O_4 \cdot H_2O$, M_r 285.3, *mp* 257 – 257.5 °C, is an adenosine analogue produced by *Streptomyces antibioticus*. Its mechanism of action is similar to that of idoxuridine. The number and severity of adverse reactions of the two drugs are not significantly different, although vidarabine has been used to treat cases unresponsive to idoxuridine [61]. Vidarabine is available as a 3 % ointment. See also ⟶ .

Trade name: Vira-A (Parke-Davis).

[Top of Page]

4. Anti-inflammatory Agents

A variety of agents are available for the treatment of ocular inflammatory conditions, including corticosteroids, nonsteroidal anti-inflammatory agents that block mediator synthesis or release, and, more rarely, immunosuppressive agents. For general information, see ⟶ Anti-inflammatory–Antirheumatic Drugs.

4.1. Corticosteroids

For general information, see ⟶ Hormones – Adrenal Steroid Hormones .

Corticosteroids are widely used for the treatment of ocular inflammation [62-64]. Prednisolone, hydrocortisone, dexamethasone, medrysone, and fluorometholone are available in topical ocular preparations (suspension, ointment, or solution). In certain cases, topical application may be supplemented or replaced by systemic or periocular administration (e.g., severe anterior uveitis and inflammation of the posterior segment, optic nerve, or orbit) [62], [63].

The use of corticosteroids is not without potential ocular and systemic side effects (e.g., elevated intraocular pressure, posterior subcapsular cataracts, and inhibition of epithelial wound healing [60], [62], [65-67]). Because corticosteroids have immunosuppressive properties, resistance to infection is lowered. Accordingly, a number of ophthalmic preparations containing combinations of corticosteroids and antimicrobial agents are available for anti-inflammatory/anti-infective therapy (Tables 2 and 3).

Table 2. Steroid and antibiotic drops

Product	Steroid	Antibiotic	Company
Chlormycetin Hydrocortisone Powder	0.5% hydrocortisone acetate	0.25% chloramphenicol	Parke-Davis
Neo-Cortef Suspension	0.5% hydrocortisone acetate	neomycin sulfate equivalent to 0.35% base	Upjohn
Bacticort Suspension	1% hydrocortisone	neomycin sulfate equivalent to 0.35% base and 10000 units polymyxin B sulfate/mL	Rugby
Triple-Gen Suspension	1% hydrocortisone	neomycin sulfate equivalent to 0.35% base and 10000 units polymyxin B sulfate/mL	Goldline
Cortisporin Suspension	1% hydrocortisone	neomycin sulfate equivalent to 0.35% base and 10000 units polymyxin B sulfate/mL	Burroughs Wellcome
Terra-Cortil Suspension	1.5% hydrocortisone acetate	0.5% oxytetracycline	Roerig
Ak-Neo-Cort Suspension	1.5% hydrocortisone acetate	neomycin sulfate equivalent to 0.35% base	Akorn
Cor-Oticin Suspension	1.5% hydrocortisone acetate	neomycin sulfate equivalent to 0.35% base	Americal
Ortho Drops Suspension	1.5% hydrocortisone acetate	neomycin sulfate equivalent to 0.35% base	Vortech
Poly-Pred Suspension	0.5% prednisolone acetate	neomycin sulfate equivalent to 0.35% base and 10000 units polymyxin B sulfate/mL	Allergan
Pred-G Suspension	1% prednisolone acetate	gentamycin sulfate equivalent to 0.3% gentamycin base	Allergan
NeoDecadron Solution	0.1% dexamethasone phosphate	neomycin sulfate equivalent to 0.35% base	MSD
TobraDex Suspension	0.1% dexamethasone	0.3% tobramycin	Alcon
Dexasporin Suspension	0.1% dexamethasone	neomycin sulfate equivalent to 0.35% base and 10000 units polymyxin B sulfate/mL	Pharmafair, Rugby, and others
Ak-Trol Suspension	0.1% dexamethasone	neomycin sulfate equivalent to 0.35% base and 10000 units polymyxin B sulfate/mL	Akorn
Dexacindin Suspension	0.1% dexamethasone	neomycin sulfate equivalent to 0.35% base and 10000 units polymyxin B sulfate/mL	IOLAB
Maxitrol Suspension	0.1% dexamethasone	neomycin sulfate equivalent to 0.35% base and 10000 units polymyxin B sulfate/mL	Alcon

Table 3. Steroid and antibiotic ointments

Product	Steroid	Antibiotic	Company
Orthocort	0.5% hydrocortisone acetate	1% chloramphenicol and 10000 units polymyxin B/g	Parke-Davis
Cortisporin	1% hydrocortisone	neomycin sulfate equivalent to 0.35% base, 400 units bacitracin zinc, and 10000 units polymyxin B sulfate/g	Burroughs Wellcome
Coracin	1% hydrocortisone acetate	0.5% neomycin sulfate, 400 units bacitracin zinc and 10000 units polymyxin B sulfate/g	Coracin
NeoDecadron	0.05% dexamethasone phosphate	neomycin sulfate equivalent to 0.35% neomycin base	MSD
AK-Trol	0.1% dexamethasone	neomycin sulfate equivalent to 0.35% base and 10000 units polymyxin B sulfate/g	Akorn
Dexacidin	0.1% dexamethasone	neomycin sulfate equivalent to 0.35% base and 10000 units polymyxin B sulfate/g	IOLAB
Dexasporin	0.1% dexamethasone	neomycin sulfate equivalent to 0.35% base and 10000 units polymyxin B sulfate/g	Pharmafair, Rugby, and others
Maxitrol	0.1% dexamethasone	neomycin sulfate equivalent to 0.35% base and 10000 units polymyxin B sulfate/g	Alcon

Hydrocortisone [50-23-7], 17-hydroxycorticosterone, cortisol, $C_{21}H_{30}O_5$, M_r 362.5. See also ⟶ Hormones – Naturally Occurring Glucocorticoids.

Hydrocortisone (1 %) is available in antimicrobial – anti-inflammatory ointment or suspension combination products (Tables 2 and 3).

Trade names: Ak-Spore ointment (Akorn; hydrocortisone, neomycin sulfate and polymyxin B sulfate); Cortisporin ointment (Burroughs Wellcome: hydrocortisone, polymyxin B sulfate, neomycin sulfate, and bacitracin zinc); Cortisporin suspension (Burroughs Wellcome: hydrocortisone, neomycin sulfate, and polymyxin B sulfate); Ocu-Cort ointment (Ocumed: hydrocortisone, polymyxin B sulfate, neomycin sulfate, and bacitracin zinc); Ocutricin HC ointment (Pharmafair: hydrocortisone, bacitracin zinc, polymyxin B sulfate, and neomycin sulfate); Ocutricin HC suspension (Pharmafair: hydrocortisone, neomycin sulfate, and polymyxin B sulfate).

Hydrocortisone acetate [50-03-3], hydrocortisone 21-acetate, cortisol acetate, $C_{23}H_{32}O_6$, M_r 404.5.

Trade names: Hydrocortone (Merck Sharp & Dohme), Optef (Upjohn); also see Tables 2 and 3.

Prednisolone [50-24-8], 1,2-dehydrohydrocortisone, $C_{21}H_{28}O_5$, M_r 360.5. See also ⟶ Hormones.

Prednisolone acetate [52-21-1], prednisolone 21-acetate, $C_{23}H_{30}O_6$, M_r 402.5.

Trade names: Ak-Tate (Akorn); Econopred, Econopred Plus (Alcon); Ocu-pred A (Ocumed); Pred Forte, Pred Mild (Allergan); see also Tables 2 and 3.

Prednisolone sodium phosphate [125-02-0], prednisolone 21-(disodium orthophosphate), $C_{21}H_{27}Na_2O_8P$, M_r 484.4, is water soluble and is available as solutions.

Trade names: Ak-Pred — 0.125 % and 1 % (Akorn); I-Pred and I-Pred 1 % (Americal); Inflamase Forte 1 %, Inflamase Mild (IOLAB); Ocu-Pred, Ocu-Pred Forte (Ocumed); Predair, Predair Forte (Pharmafair); see also Tables 2 and 3.

Dexamethasone [50-02-2], 9 α-fluoro-16 α-methylprednisolone, $C_{22}H_{29}FO_5$, M_r 392.5. See also ⟶ Hormones.

Trade names: Ak-Dex, Ak-Trol (Akorn); Baldex (Bausch & Lomb); Dexacidin (IOLAB); Decadron Phosphate (Merck Sharp & Dohme); Dexair (Pharmafair); Dexasporin (Pharmafair); Infectrol (Bausch & Lomb); Maxidex, Maxitrol (Alcon); I-Methasone (Americal); Ocu-Trol (Ocumed); Tobradex (Alcon); see also Tables 2 and 3.

Medrysone [2668-66-8], 11 β-hydroxy-6 α-methylprogesterone, $C_{22}H_{32}O_3$, M_r 344.5.

Trade names: HMS Liquifilm, Ipoflogin (Allergan); Medrifar (Farmila); Medriusar (Difa); Ophtocortin (Winzer); Sedesterol (Poen); Spectramedryn (Allergan); Visudrisone (LOA).

Fluorometholone [426-13-1], $C_{22}H_{29}FO_4$, M_r 376.5, is used ophthalmically as a 0.1 or 0.25 % suspension or as a 0.1 % ointment. See also ⟶ Hormones.

Trade names: Flucon, Isopto-Flucon (Alcon); FML Liquifilm, FML Forte Liquifilm, FML S.O.P. (Allergan); Fluor-Op (IOLAB).

4.2. Miscellaneous Anti-inflammatory Agents

Disodium cromoglycate [15826-37-6], DSCG, cromolyn sodium, sodium cromoglycate, $C_{23}H_{14}Na_2O_{11}$, M_r 5123, appears to achieve its antiallergic and anti-inflammatory effects by stabilizing mast cells and inhibiting antigen-induced mast cell degranulation and the associated release of a variety of inflammatory mediators [62], [68]. See also ⟶ Antiallergic Agents – Mast Cell Stabilizing Agents. Topical ophthalmic DSCG (Opticrom, Fisons) is available for prophylactic treatment of allergic disorders such as vernal or allergic keratoconjunctivitis. Maintaining DSCG therapy throughout the allergy season may be more advantageous than sporadic treatment of flare-ups [68]. Therapy with DSCG may permit the reduction or elimination of topical corticosteroid treatment [62].

Trade names: Opticrom (Fisons), Vividrin (Mann).

Nonsteroidal anti-inflammatory drugs (NSAIDs) inhibit the enzyme cyclooxygenase, which is responsible for the first step in the synthesis of prostaglandins from arachidonic acid. The prostaglandins mediate certain steps of the inflammatory process. The role of arachidonic acid metabolites in ocular inflammation and pressure elevation continues to emerge [62]. Oral administration of NSAIDs has been approached as an alternative to corticosteroid anti-inflammatory therapy [62], [65]. Oral administration of classical cyclooxygenase inhibitors (e.g., acetylsalicyclic acid and indomethacin) has met with mixed success in the treatment of ocular inflammation, partially due to systemic intolerance (e.g., gastrointestinal side effects). A number of more recently developed NSAIDs such as diflusinal (Dolobid) and naproxen (Naprosyn) may be better tolerated orally.

Flurbiprofen [5104-49-4], 2-fluoro- α-methyl-(1,1′-biphenyl)-4-acetic acid, $C_{15}H_{13}FO_2$, M_r 244.3. The sodium salt dihydrate of flurbiprofen is available as an ophthalmic solution (0.03 %) for topical application (Ocufen Liquifilm, Allergan) for inhibition of intraoperative miosis.

Tetracycline (see Section Tetracycline Antibiotics) is used to treat ocular rosacea [69].

Immunosuppressive agents, including alkylating agents such as cyclophosphamide, the folic acid antimetabolite methotrexate, and the antibiotic cyclosporin A, are systemically cytotoxic and dangerous drugs. Although their use in ocular therapy is rare, some of them have been used to treat intractable and progressively destructive ocular conditions [65].

[Top of Page]

5. Antiglaucomatous Agents

Glaucoma is a leading cause of blindness and may be defined as a loss of visual function and optic nerve damage associated with an elevated intraocular pressure (IOP). Ocular hypertension alone is not predictive of glaucoma or visual impairment [70]. In a healthy eye, the IOP (ca. 2 – 2.6 kPa, 15 – 20 mm Hg) [71] is maintained by a balance of aqueous humor formation and outflow. Glaucoma therapy often involves a reduction in IOP by increasing outflow or decreasing production. A variety of therapeutic agents have ocular hypotensive effects [68-74] and include adrenergic agents, miotics, carbonic anhydrase inhibitors, and hyperosmotic agents. The applications and adverse effects of ocular hypotensives are discussed in [70-80].

Glaucoma associated with congenital ocular abnormalities is treated surgically or with a combination of surgical and medical therapy. Glaucomas may be classified as primary (direct disturbance of the

aqueous circulation) or secondary (arising from other disease states). They are also classified as open angle or narrow angle, depending on the anterior chamber angle (the anatomy of the structures within the angle of the eye as visualized by gonioscopy). These classifications are important in determining whether surgery or drug therapy should be employed and which ocular hypotensive drug therapies may be appropriate.

5.1. Sympathomimetic Drugs

Epinephrine [51-43-4], adrenaline, $C_9H_{13}NO_3$, M_r 183.2, is used widely in primary open-angle glaucoma but is contraindicated in narrow-angle glaucoma [70], [71] because of its mydriatic effects (dictation of the pupil). Topically applied epinephrine has mydriatic, vasoconstricting, and ocular hypotensive effects. Although its mechanism of action is not fully understood, it may lower the IOP by reducing aqueous humor production and also increasing outflow [70-74]. Epinephrine is often used in combination with other ocular hypotensives (e.g., pilocarpine).

Trade names: Simplene (Smith & Nephew), 1 and 2 % solutions (Pharmafair); U.S.P. Ophthalmic Solution: a solution of epinephrine prepared with hydrochloric acid.

Epinephrine hydrochloride [55-31-2], Epifrin (0.25, 0.5, 1, or 2 %; Allergan), Glaucon (1 or 2 %; Alcon).

Epinephrine bitartrate [51-42-3], adrenaline bitartrate, $C_9H_{13}NO_3 \cdot C_4H_6O_6$, M_r 333.3, Epitrate (Wyeth-Ayerst). Epinephrine bitartrate is also available in combination with pilocarpine hydrochloride (E-Pilo-1 – 6, IOLAB)

Epinephryl borate [5579-16-8] : Eppy/N (0.5, 1.0, and 2 %, Sola/Barnes Hind).

Dipivefrin hydrochloride [52365-63-6], dipivalylepinephrine hydrochloride, dipivalyladrenaline hydrochloride, $C_{19}H_{29}O_5N \cdot HCl$, M_r 387.9. For synthesis, see [81]. Dipivefrin hydrochloride is a dipivalyl prodrug that is converted to epinephrine by esterase action. It has enhanced corneal penetration and hypotensive potency relative to epinephrine [71], [73]. Dipivefrin 0.1 % is about as potent as 2 % epinephrine.

Trade names: Epifrin (Allergan), Glaucothil (Thilo), Glaudrops (Cusi), Propine (Allergan).

5.2. β-Adrenergic Blocking Agents

Although systemic blockers of the β-adrenoceptors are not approved for ocular hypotensive indications, some reduce IOP in addition to having cardiovascular activity against arrhythmias, angina, and hypertension. The β-blockers lower the IOP by decreasing aqueous humor production [72-74]. Although topical preparations are generally well tolerated, systemic (CNS, cardiovascular, and respiratory) side effects have been observed [72-74], [76-78].

Timolol maleate [26921-17-5] (timolol [26839-75-8]), (*S*)-1-[(1,1-dimethylethyl)amino]-3-[(4-morpholinyl-1,2,5-thiadiazol-3-yl)oxy]-2-propanol maleate, $C_{13}H_{24}N_4O_3S \cdot C_4H_4O_4$, M_r 432.5, is available as 0.25 and 0.5 % solutions. For synthesis, see [82]. See also ⟶ Antihypertensives – Timolol Timolol can provide an additive effect when used concurrently with other ocular hypotensive agents such as miotic agents or carbonic anhydrase inhibitors, although the effects with epinephrine are more controversial [72-74].

Trade names: Timoptic, Timoptol (Merck Sharp & Dohme).

Levobunolol hydrochloride [27912-14-7] (levobunolol [47141-42-4]), (–)-bunolol hydrochloride, (–)-5-[3-(*tert*-butylamino)-2-hydroxypropoxy]-3,4-dihydro-1(2*H*)-naphthalenone hydrochloride, $C_{17}H_{25}NO_3 \cdot HCl$, M_r 327.9. For synthesis, see [83].

Trade name: Betagan (0.5 %, Allergan).

Betaxolol hydrochloride [63659-19-8] (betaxolol [63659-18-7]), 1-[4-[2-(cyclopropylmethoxy)ethyl]phenoxy]-3-isopropylamino-2-propanol hydrochloride, $C_{18}H_{29}NO_3 \cdot HCl$, M_r 343.9. For synthesis, see [84].

Trade name: Betoptic (0.5 % Alcon).

Metipranolol [22664-55-7], 4-(2-hydroxy-3-isopropylaminopropoxy)-2,3,6-trimethylphenyl acetate, $C_{17}H_{27}NO_4$, M_r 309.4. For synthesis, see [85], [86].

Trade names: Betamann, Beta-Ophtiole (Mann); Glauline, Minims Metipranolol (Smith & Nephew); Optipranolol (Bausch & Lomb); Normoglaucon (Mann).

5.3. Carbonic Anhydrase Inhibitors

Carbonic anhydrase inhibitors decrease the IOP by blocking bicarbonate formation in the ciliary process required for aqueous humor production [74], [79]. These agents are administered systemically and are useful in treating glaucoma cases that do not respond to topical therapy [72], [74]. Virtually all (90 – 99 %) of the carbonic anhydrase activity must be blocked before the IOP is lowered [72], [79], and oral doses are usually administered several times a day. The sulfonamide carbonic anhydrase inhibitors are diuretics that are readily absorbed from the gastrointestinal tract. Effective oral doses of these agents for glaucoma therapy depend on their pharmacokinetic properties [72], [74], [79]. Systemic side effects [72], [74], [76], [79] may limit the use of oral carbonic anhydrase inhibitors, especially in the elderly. Unfortunately, no topically effective preparations of these agents are available, possibly due to poor corneal penetration. Orally administered carbonic anhydrase inhibitors may provide additive effects when used in combination with topically applied antiglaucoma agents (e.g., pilocarpine and timolol) [74], [79].

Acetazolamide [59-66-5], 2-acetylamino-1,3,4-thiadiazole-5-sulfonamide, $C_4H_6N_4O_3S_2$, M_r 222.2. See also ⟶ Diuretics – Carbonic Anhydrase Blockers.

Trade names: Acetamide (Nessa); Diamox, Diamox Sequels (Lederle); Diuriwas (IFI); Edemox (Wasserman); Glaupax (Erco, Dispersa); Theraplix (Cycanamide, Cyanamide-Novalis).

Dichlorphenamide [120-97-8], 4,5-dichloro-1,3-benzenedisulfonamide, $C_6H_6Cl_2N_2O_4S_2$, M_r 305.2. For synthesis, see [87].

Trade names: Antidrasi (ISF, Merck Sharp & Dohme); Daranide (Merck Sharp & Dohme); Fenamide (Farmigea); Glauconide (Llorens); Glaumid (SIFI); Hipotensor Oftalmico, Oralcon, Oratrol (Alcon).

Methazolamide [554-57-4], *N*-[5-(aminosulfonyl)-3-methyl-1,3,4-thiadiazol-2(3*H*)-ylidene]-acetamide, $C_5H_8N_4O_3S_2$, M_r 236.3. For synthesis, see [88].

Trade names: Neptazane, Theraplix (Lederle).

5.4. Hyperosmotic Agents

Orally (glycerol, isosorbide, urea) or intravenously (mannitol) administered hyperosmotic agents produce a rapid reduction of IOP as a result of migration of water from the eye to ocular blood vessels [72], [75]. These drugs may have significant side effects [72], [75], [76]. They are used primarily to treat acute IOP elevation and in ocular surgical procedures [72].

Glycerol [56-81-5], propane-1,2,3-triol, $C_3H_8O_3$, M_r 92.1.

Trade names: Ophthalgan (Wyeth-Ayerst), Osmoglyn (Alcon).

Isosorbide [652-67-5], 1,4:3,6-dianhydrosorbitol, $C_6H_{10}O_4$, M_r 146.1.

Trade name: Ismotic (Alcon).

Mannitol [69-65-8], cordycepic acid, mannite, $C_6H_{14}O_6$, M_r 182.2.

Trade name: Mannitol Injection (Astra).

Urea [57-13-6], carbamide, ureum, CH_4N_2O, M_r 60.1.

Trade name: Ureaphil (Abbott).

5.5. Miotics (Parasympathomimetic Agents)

Miotics are agents that cause constriction of the pupil. Two classes of miotics, cholinergics and anticholinesterases (parasympathomimetic agents), have therapeutic roles in glaucoma. Acetylcholine itself is not generally useful because of its short biological half-life and topical ineffectiveness, although it can induce miosis when applied directly to the iris during surgery [73]. Cholinergic agonists (pilocarpine, carbachol) act directly on cholinergic effector cells to mimic the effects of acetylcholine; anticholinesterases (physostigmine, demecarium bromide, echothiophate iodide, isoflurophate) prolong the action of endogenous acetylcholine by blocking its hydrolysis by cholinesterases. In the eye, miotics appear to reduce IOP through activation of muscarinic acetylcholine receptors, which contract the ciliary muscle and enhance flow through the trabecular meshwork. Muscarinic activation also constricts the pupillary sphincter and produces miosis, which is sometimes an undesirable side effect of antiglaucoma therapy. Other ocular and systemic side effects may be associated with the use of miotics for antiglaucoma therapy [72], [73], [76], [77], [80].

5.5.1. *Cholinergic Agonists*

Carbachol [51-83-2], *O*-carbamoylcholine chloride, $C_6H_{15}ClN_2O_2$, M_r 182.7. Carbachol is inherently more potent and longer acting than pilocarpine but has poorer corneal penetration and more severe ocular side effects. Enhancement of corneal penetration may be achieved with 0.03 % benzalkonium chloride (BAK) in the formulation, or with lower levels of BAK along with methyl cellulose or hydroxypropyl methyl cellulose to prolong contact with the ocular surface [73]. Carbachol is used when the response to pilocarpine is inadequate or when a pilocarpine allergy develops [73], [76].

Trade names: Isopto Carbachol (Alcon), also available as a 0.01 % solution; Miostat (Alcon) for intraocular injection for miosis during surgery.

Pilocarpine [92-13-7], (3*S*,4*R*)-3-ethyldihydro-4-[(1-methyl-1*H*-imidazol-5-yl)methyl]furan-2(3*H*)-one, $C_{11}H_{16}N_2O_2$, M_r 208.3. Pilocarpine is one of the most useful drugs for management of glaucomas, including primary open-angle and acute angle-closure glaucomas [72], [73]. Principal ocular side effects of pilocarpine solutions (0.25 – 10 %) include miosis, ciliary spasm, and visual blurring [72], [73], [76]. A sustained-release drug delivery system (Ocusert) for pilocarpine base is also available [72], [73], [76].

Trade names: Ocusert Pilo-20 and Ocusert Pilo-40 Ocular Therapeutic System (20 or 40-µg pilocarpine delivery per hour for one week, Alza).

Pilocarpine hydrochloride [54-71-7], $C_{11}H_{16}N_2O_2 \cdot HCl$, M_r 244.7.

Trade names: Akarpine (Akorn); I-Pilocarpine (Americal); Isopto Carpine (Alcon); Ocu-Carpine (Ocumed); Pilocar (IOLAB); Pilokair (Pharmafair); Pilopine (Alcon), and in various combinations with epinephrine bitartrate: E-Pilo-1 – 6 (IOLAB).

Pilocarpine nitrate [148-72-1], $C_{11}H_{16}N_2O_2 \cdot HNO_3$, M_r 271.3.

Trade name: Pilagan Liquifilm (Allergan).

5.5.2. *Anticholinesterases*

Anticholinesterases may be divided into two classes. The short-acting “reversible” inhibitors (e.g., physostigmine and demecarium) transfer a carbamoyl group to the enzyme, which is removed within a few

hours to regenerate the enzyme. The long-acting irreversible inhibitors (e.g., echothiophate and isoflurophate) phosphorylate the enzyme, and cholinesterase activity is restored only through synthesis of new enzyme.

The anticholinesterases are contraindicated for angle-closure glaucoma [72], and their ocular use may produce a variety of systemic and ocular side effects [72], [73], [76]. Anticholinesterases are used primarily when other antiglaucoma medications have failed and are the least commonly used antiglaucoma agents [72].

Physostigmine [57-47-6], eserine, $C_{15}H_{21}N_3O_2$, M_r 275.4.

Trade names: Eserine sulfate (0.25 %) Sterile Ophthalmic Ointment (IOLAB).

Demecarium bromide [56-94-0], $C_{32}H_{52}Br_2N_4O_4$, M_r 716.6.

Trade names: Humorsol (Merck Sharp & Dohme), Tosmilen (Chem Linz, Sinclair).

Echothiophate iodide [513-10-0] (echothiophate [6736-03-4]), mercaptoethyltrimethylammonium iodide *O*,*O*-diethyl phosphorothioate, $C_9H_{23}INO_3PS$, M_r 383.2.

Trade names: Echofilina, Iodeto de fosfolina, Phospholine (Sodip); Phospholine Iodide (Wyeth-Ayerst, Promedica, Chinoin); Phospholinjodid (Winzer).

Isoflurophate [55-91-4], diisopropyl flurophosphate, $C_6H_{14}FO_3P$, M_r 184.1.

Trade names: Diflupyl (Labaz), DFP-Oel (Winzer), Floropryl (Merck Sharp & Dohme).

[Top of Page]

6. Mydriatics and Cycloplegics

Mydriatic and cycloplegic agents are used routinely in ophthalmic practice for dilating the pupil to facilitate examination of the retina [89-98]. In addition to dilation, cycloplegics cause paralysis of accommodation for near vision and are used primarily as an aid in refraction and in the treatment of uveitis [97]. They are also used as postoperative agents in cataract and retinal detachment surgery.

Mydriatics and cycloplegics are divided into sympathomimetics and parasympatholytics. They can be used alone or in combination. Sympathomimetic agents imitate (direct acting) or potentiate (indirect acting) the action of norepinephrine at sympathetic nerve terminals and produce mydriasis by stimulating the iris dilator muscle fibers. Parasympatholytic agents block the action of acetylcholine at the neuromuscular junction and produce pupil dilation with loss of accommodation by immobilizing the iris sphincter and ciliary muscle.

Although serious side effects from mydriatics and cycloplegics are rare, individual response to these drugs varies [98]. They should be used with caution in patients with closed-angle glaucoma or in patients with a narrow angle between the iris and the cornea because they may increase the IOP and precipitate an acute attack [98].

6.1. Sympathomimetics

Phenylephrine hydrochloride [61-76-7], (*S*)-1-(3-hydroxyphenyl)-2-methylaminoethanol hydrochloride, $C_9H_{13}NO_2 \cdot HCl$, M_r 203.7. Phenylephrine hydrochloride is used topically (2.5 and 10 % solutions) to dilate the pupil both for ophthalmoscopy in the treatment of uveitis and for cataract surgery [97]. Maximum dilation occurs within 45 – 60 min and recovery in about 6 h. A 1 % solution can be used in the diagnosis of Horner's syndrome [97].

Trade names: Ak-Dilate, Ak-Vernacon (Akorn); Blephamide (Allergan); I Phrine (Americal); Isonefrine (Allergan); Isopto Frin (Alcon); Minims Phenylephrine Hydrochloride (Smith & Nephew); Mydfrin (Alcon); Neosynephrine (Winthrop); Opstin (Allergan); Phenylephrine Hydrochloride (IOLAB); Prefin (Allergan); Vasosulf (Cooper Vision); Vistosan (Allergan); Zincfrin (Alcon).

Hydroxyamphetamine hydrobromide [306-21-8], (±)-4-(2-aminopropyl)phenol hydrobromide, $C_9H_{13}NO \cdot HBr$, M_r 232.1. For synthesis, see [99]. Hydroxyamphetamine hydrobromide is an indirect-acting sympathomimetic agent. It is used in a 1 % solution as a mydriatic (effect comparable to 2.5 % phenylephrine) and in the diagnosis of Horner's syndrome [98]. Hydroxyamphetamine hydrobromide may be used in patients allergic to phenylephrine.

Trade name: Paredrine (SKF).

Cocaine [53-21-4], $C_{17}H_{21}NO_4 \cdot HCl$, M_r 339.8, is an indirect-acting sympathomimetic agent. In addition to its mydriatic action, it is also a local anesthetic and vasoconstrictor. Cocaine is not available commercially as a solution for clinical use.

6.2. Parasympatholytics

Atropine sulfate [5908-99-6] (monohydrate [55-48-1]), $(C_{17}H_{23}NO_3)_2 \cdot H_2SO_4 \cdot H_2O$, M_r 694.8. See also ⟶ Alkaloids – Pyridine Alkaloids; ⟶ Antiasthmatic Agents. Atropine is the most effective cycloplegic agent and has the longest duration of action. It is used to maintain a dilated pupil after intraocular surgery. Pupil dilation occurs within 30 – 40 min and lasts up to 2 weeks.

Trade names: Alcon Opulets Atropine 1 % (Alcon); Atropine-Care Ophthalmic (Akorn); Atropine Minims (Smith & Nephew); Atropine Sulfate Ophthalmic (Alcon, Allergan, Moore, Rugby, Schein, Steris, Balon, Fougera, Lilly); Atropine Sulfate S.O.P. (Allergan); Atropisol (IOLAB); Cicloplegyl (Winzer); Isopto Atropine (Alcon); I-Tropine (Americal); Minims Atropine Sulfate (Smith & Nephew); SMP Atropine (Cooper Vision).

Cyclopentolate hydrochloride [5870-29-1], $C_{17}H_{25}NO_3 \cdot HCl$, M_r 327.9. For synthesis, see [100]. Cyclopentolate hydrochloride has a rapid onset (30 – 60 min) but shorter duration of action (< 24 h) than atropine [97].

Trade names: Alcon Opulets Cyclopentolate (Alcon); Ak-Pentolate (Akorn); Ciclolux (Allergan); Ciclopegic, Colircusi ciclopejico, Colirio Oculos Cicloplegic (Llorens), Cyclopen, Cyclopentol Colircusi, Cyclomydril, Cyclogyl (Alcon); Cyclopentolat Minims, Cyplegin, Mydplegin, Minims Cyclopentalate Hydrochloride (Smith & Nephew); Mydrilate (Boehringer, Ingelheim); Skiacol (Pos); Zyklolat (Mann).

Homatropine hydrobromide [51-56-9], $C_{16}H_{21}NO \cdot HBr$, M_r 356.3. Homatropine hydrobromide is weaker and less toxic than atropine. The onset of action occurs in about 15 – 20 min and lasts ca. 3 h. Complete recovery time is about 36 – 48 h. Homatropine is used for refraction, in the treatment of inflammatory conditions of the uveal tract, and as a pre- and postoperative agent. It is also used as an optical aid for axial lens opacities [97].

Trade names: Ak-Homatropine (Akorn), Allergan Homatropine (Allergan), Ancatropine Infant Drops (Anca), Homatrine (Americal), Homatropine HBr Ophthalmic (IOLAB), Isopto Homatropine (Alcon), Minims Homatropine Hydrobromide (Smith & Nephew).

Scopolamine hydrobromide [114-49-8], (trihydrate [6533-68-2]), $C_{17}H_{21}NO_4 \cdot HBr \cdot 3\ H_2O$, M_r 438.3. See also ⟶ Alkaloids – Chemical and Physical Properties. Scopolamine hydrobromide is an effective cycloplegic and is used in the treatment of uveitis, in refraction of children, postoperatively, and in patients sensitive to atropine. Mydriasis and cycloplegia occur within 20 – 60 min and last 3 – 7 d. The duration of action is much shorter in eyes with inflammation.

Trade names: Contac (Allergan), Isopto Hyoscine (Alcon), Minims Hyoscine Hydrobromide (Smith & Nephew), Murocoll-2 (Bausch & Lomb).

Tropicamide [1508-75-4], *N*-ethyl-*N*-(4-pyridylmethyl)tropamide, $C_{17}H_{20}N_2O_2$, M_r 284.4. For synthesis, see [101]. Tropicamide is used as a shorter-acting substitute for atropine or scopolamine when prolonged mydriasis and cycloplegia are not required. It is an effective mydriatic with weak cycloplegic activity and is, therefore, useful for ophthalmoscopy and some preoperative and postoperative states. Onset of mydriasis takes place within 15 – 20 min and lasts ca. 7 h [98]. Mydriasis may be counteracted by local application of pilocarpine. Maximum cycloplegia occurs within 20 – 25 min; the duration of this peak effect is 15 – 20 min and has passed in 6 – 8 h.

Trade names: I-Picamide (Americal), Minims Tropicamide (Smith & Nephew), Mydriacyl (Alcon), Mydrian (Dispersa), Mydriaticum (Merck Sharp & Dohme), Phenyltrope (Akorn), Tropicacyl (Akorn), Tropikamid Minims (Smith & Nephew), Tropimil (Farmigea), Visumidriatic (Merck Sharp & Dohme).

[Top of Page]

7. Vasoactive (Adrenergic) Agents

In addition to their mydriatic effect, adrenergic agents constrict the vascular system of the conjunctiva within minutes (α-adrenergic effect) and are used to treat congestion and relieve minor allergy irritation and itching of the conjunctiva. Commercially available ophthalmic vasoconstrictive agents usually contain ephedrine, naphazoline, oxymetazoline, phenylephrine, or tetrahydrozoline. Side effects are not typically observed because of the relatively low concentrations used but rebound congestion can occur with extended use [97].

Naphazoline hydrochloride [550-99-2], 2-(1-naphthylmethyl)-2-imidazoline hydrochloride, $C_{14}H_{14}N_2 \cdot HCl$, M_r 246.7. For synthesis, see [102]. One or two drops of naphazoline solution (0.012 – 0.1 %) are administered in the eye every 3 – 4 h.

Trade names: Ak-Con (Akorn); Albalon (Allergan); Allerest Eye Drops (Pharmacraft); Allergy Drops (Bausch & Lomb); Clear Eyes (Ross); Clera (Person and Covey); Comfort Eye Drops, Degest 2 (Barnes-Hind); Imidazyl (Allergan); Naphcon (Alcon); I-Naphline (Americal); Opcon (Bausch & Lomb); Optazine (Lederle); Otrivin, Privin, Privina, Privine (Ciba); Vasocon Regular (IOLAB).

Naphazoline formulations that also contain an antihistamine are also available: Ak-Con-A (Akorn); Opcon-A (Bausch & Lomb); Naphcon-A, Vasocon-A (IOLAB); Vasoclear (IOLAB); Vistalbalon, Albalon A Liquifilm (Allergan); Zincfrin-A also contains zinc sulfate (Alcon).

Oxymetazoline hydrochloride [2315-02-8], 2-(4-*tert*-butyl-3-hydroxy-2,6-dimethylbenzyl)-2-imidazoline hydrochloride, $C_{16}H_{24}N_2O \cdot HCl$, M_r 296.8.

Trade names: Ocuclear Eye Drops (Schering), Visine L.R. Eye Drops (Pfizer).

Phenylephrine hydrochloride [61-76-7], (*S*)-1-(3-hydroxyphenyl)-2-methylaminoethanol hydrochloride, $C_9H_{13}NO_2 \cdot HCl$, M_r 203.7. Phenylephrine is used at a concentration of 0.12 %. This relatively low concentration causes vasoconstriction with little or no pupillary dilation. One or two drops are instilled in the eye(s) three or four times daily to relieve burning and itching in mild cases of noninfectious conjunctivitis.

Trade names: Ak-Dilate, Ak-Vernacon, Ak-Nephrin, (Akorn); Isonefrine (Allergan); Isopto Frin, Isopto Phenylephrine (Alcon); Metaoxedrin Minims, Minims Phenylephrine Hydrochloride (Smith & Nephew); Mydfrin (Alcon); Ocu-Phrin (Ocumed); Optistin, Prefrin, Prefrin Liquifilm, Prefrin-A, Prefrin-Z (Allergan); Vasosulf (CooperVision); Relief (Allergan); Zincfrin (Alcon).

Tetrahydrozoline hydrochloride [522-48-5], 2-(1,2,3,4-tetrahydro-1-naphthyl)-2-imidazoline hydrochloride, $C_{13}H_{16}N_2 \cdot HCl$, M_r 236.7. For synthesis, see [103]. Tetrahydrozoline hydrochloride solutions (0.05 %) are used to decrease swelling of the mucosa in conjunctivitis. One or two drops are instilled in the eye up to four times daily. The onset of vasoconstriction becomes apparent within minutes.

Trade names: Berberin Ophtiole (Mann); Collyrium (Wyeth); Optigene 3 (Pfeiffer); Mallazine Drops (Hauck); Murine (Abbott); Murine Plus (Ross); Soothe Eye Drops (Alcon); Visine A.C., Visine Eye Drops (Leeming); Visine Plus (G.P. Laboratories).

[Top of Page]

8. Diagnostic Agents

Diagnostic agents are used to examine the eye for signs of systemic disease and to diagnose ocular abnormalities. Dyes used for this purpose include fluorescein, rose bengal, indocyanine green [3599-32-4], trypan blue [72-57-1], alcian blue [12040-44-7], methylene blue [61-73-4], and fluorexon. Of these, only fluorescein, rose bengal, and fluorexon are commercially available [104], [105]. Several drugs are also used as ophthalmic diagnostic agents, including edrophonium chloride, methacholine, and pilocarpine.

Fluorescein C.I. 45 350 [2321-07-5] (fluorescein sodium [518-47-8]), $C_{20}H_{12}O_5$, M_r 332.3, *mp* 314 – 316 °C (decomp.). The synthesis, properties, and histological uses of fluorescein have been reviewed [106], [107]. Fluorescein sodium is used typically as a 1 or 2 % solution or as impregnated filter paper strips for detecting foreign bodies and examination of the corneal surface. During corneal surgery, topical administration of fluorescein can be used to detect leakage from the anterior chamber. In cataract surgery, leaks are detected as bright green rivulets [104], [105].

Fluorescein is used for the fitting and management of hard contact lenses. In the presence of fluorescein the tear layer fluoresces green under a cobalt blue light and contrasts with a blue fluorescence or the absence of fluorescence where the lens comes in contact with the cornea. Fluorescein is not useful for fitting soft contact lenses because it penetrates the lens matrix, providing insufficient contrast between the lens and the tissue [104], [105].

Fluorescein is also used intravenously in concentrations of 5 – 25 % for examination of the ophthalmic vasculature and the presence of ocular lesions.

Trade names: Ak-Fluor (Akorn), Fluorescite (Alcon), Fluorets (Akorn), Fluor-I-Strip (Wyeth-Ayerst), Ful-Glo (Barnes-Hind), Funduscein (CooperVision); with proparacaine hydrochloride: Fluoracaine (Akorn).

Rose bengal, C.I. 45 440 [11121-48-5], (disodium salt [632-69-9]), $C_{20}H_2Cl_4I_4Na_2O_5$, M_r 1017.6. The dipotassium or disodium salt of rose bengal dissolves in water, giving a bluish red color [106]. Unlike fluorescein, rose bengal stains degenerated corneal and conjunctival epithelial tissue red. The stain intensity correlates with the state of degeneration, with dead cells staining intensely [108]. The dye is useful in highlighting abnormal epithelial cells in “dry eye” conditions. It is also a useful adjunct in determining the area of epibulbar squamous neoplasms [109].

Trade names: EV Rose Bengal (Eagle Vision), Rose Bengal (Akorn).

Fluorexon [1461-15-0], $C_{30}H_{26}N_2O_{13}$, M_r 618.54; tetrasodium salt $C_{30}H_{22}N_2Na_4O_{13}$, M_r 710.5. Unlike fluorescein, fluorexon is slow to penetrate the matrix of soft contact lens materials and may be used as an adjunct for fitting soft contact lenses. (However, it is not recommended for lenses with >60 % water content [110].)

Trade name: Fluoresoft (Holles).

Edrophonium chloride [116-38-1], ethyl-(2-hydoxyphenyl)dimethylammonium chloride, $C_{10}H_{16}ClNO$, M_r 201.7, *mp* 162 – 163 °C (decomp.). For synthesis, see [111]. Edrophonium chloride (an anticholinesterase) may be injected intravenously to determine whether the cause of ptosis (drooping of the upper eyelid) is myasthenia gravis (a neuromuscular disease).

Trade name: Enion (Anaquest), Tensilon (Roche).

Methacholine chloride [62-51-1], acetyl- β-methylcholine chloride, $C_8H_{18}ClNO_2$, M_r 195.7, *mp* 172 – 173 °C. A 2.5 % methacholine (a cholinergic drug) solution is applied topically to the conjunctival sac to diagnose Adie's pupil (a disruption of cholinergic innervation to the iris). Normal pupils do not respond significantly to methacholine, whereas the Adie's pupil responds with intense miosis.

Trade name: Provocholine (Hoffmann-La Roche).

Pilocarpine, see Section Cholinergic Agonists. A 0.1 – 0.125 % solution of pilocarpine can be used to diagnose Adie's pupil. A 0.5 – 1 % solution can be used in the differential diagnosis of the fixed, dilated pupil. The dilated pupil responds to the drug if the dilation is of neurologic origin, where it does not respond if the etiology is anticholinergic in nature [104], [112].

[Top of Page]

9. Dry Eye Medications

“Dry eye” denotes a number of conditions including insufficient lacrimation, mucin deficiency, lipid abnormality, impaired blinking, or primary ocular disorder [113]. The seriousness of dry eye ranges from mild “dry and scratchy” eyes to serious degeneration and keratinization of corneal tissue, which may lead to blindness. The latter condition is often found in developing countries in areas of malnutrition (deficiency of protein and vitamin A). However, in highly developed nations, a milder form of dry eye occurs, which is characterized by chronic eye irritation and decreased visual acuity [114]. Symptoms are normally subclinical but become symptomatic in a dry, windy, or dusty atmosphere, in air conditioning; or when contact lenses are worn.

If dietary deficiency is the underlying cause of the dry eye syndrome, a proper diet should be implemented. *trans*-Retinoic acid ointment may be applied topically to counter vitamin A deficiency [115]. In dry eye conditions induced by infection, treatment with an antimicrobial agent should be initiated.

The most common treatment of nonspecific, incipient dry eye is with tear substitutes [113]. Commercial dry eye preparations typically contain at least one *demulcent*, which lubricates and wets the eye, and a *preservative* to prevent microbial contamination of the product. Nonpreserved preparations are also available in single-dose containers. Some demulcents serve as thickening agents (e.g., substituted cellulose ethers) based on the concept that highly viscous tear substitutes should have a longer retention time in the eye. Because contact lens wearers generally experience improved comfort from the lubricant and wetting properties of demulcents, many lens preparations include one or more of these agents (see Section Disinfectants and Preservatives).

Other components of dry eye medications include *emollients* (such as petrolatum, mineral oil, and lanolin), which lubricate and protect the eye from drying, and *lipids*, which are intended to supplement a deficient superficial lipid layer of tear fluid. Both emollients and lipids may, however, interfere with visual acuity.

The most common demulcents are listed below.

Carboxymethyl cellulose sodium [9004-32-4], exists as white granules, with water solubility dependent on the degree of substitution. It is available in various viscosities.

Trade names: Bro-Lac (Riker), Celluvisc (Allergan).

Dextran [9004-54-0], a polysaccharide with a backbone of D-glucose units is produced from bacteria cultured with a sucrose substrate.

Trade names: With hydroxymethyl cellulose: Muro Tears TM (Muro), Tears Naturale R (Alcon); with hydroxypropyl methyl cellulose and dextran 70: Moisture Drops (Bausch & Lomb).

Gelatin is a mixture of water-soluble proteins obtained after collagen-containing animal tissues (e.g., skin, tendons, ligaments, bones) have been boiled with water.

Trade names: Lacril R (Allergan).

Gycerol [56-81-5], propane-1,2,3-triol, $C_3H_8O_3$, M_r 92.1.

Trade names: Dry Eye Therapy (Bausch & Lomb); with dextran 70 and hydroxypropyl methyl cellulose: Moisture Drops (Bausch & Lomb).

Ophthalmic Preparation : Glycerin Ophthalmic Solution, U.S.P.

Hydroxyethyl cellulose [9004-62-0], nearly odorless, yellowish-white, white, or grayish-white, hygroscopic granules or powder.

Trade names: Adsorbo Tears (Alcon); Lyteers (Barnes-Hind); with polyvinyl alcohol: Comfort Tears, Neo Tears (Barnes-Hind); with lipid: TearGard (Bioproducts).

Contact lens products: Soft Mate ps (Barnes-Hind), Clerz (CooperVision)

Hydroxypropyl cellulose [9004-64-2] is an off-white powder that softens at 130 °C, produces aqueous solutions with a wide range of viscosities, and precipitates from solution at 40 – 45 °C.

Trade name: Lacrisert (Merck Sharp & Dohme), a sterile (prescription only) ophthalmic insert that slowly releases hydroxypropyl cellulose.

Hydroxypropyl methyl cellulose [9004-65-3] is a powder that slowly dissolves in cold water (insoluble in hot water) to give solutions with a wide range of viscosities.

Trade names: Isopto Alkaline, Isopto Plain, Isopto Tears (Alcon); Tearisol (CooperVision); Ultratears (Alcon); with gelatin and polysorbate 80: Lacril (Allergan); with dextran: Tears Naturale (Alcon); with dextran 70 and glycerol: Moisture Drops (Bausch & Lomb).

Lens care products: With poly(vinyl alcohol): Liquifilm.

Methyl cellulose [9004-67-5], consists of white granules that are soluble in cold water (insoluble in hot water), with solubility and viscosity dependent on the degree of substitution.

Trade names: Methopto Forte (Bioproducts), Methulose (Warner-Lambert), Milroy Artificial Tears (Milroy), Murocel Ophthalmic Solution (Muro), Visculose (Warner-Lambert).

Polyethylene glycol [25322-68-3], is a clear liquid or white solid that dissolves in water to form transparent solutions of various viscosities.

Trade names: With poly(vinyl alcohol): HypoTears (CooperVision).

Contact lens products: With polyoxyl 40 stearate: Blink-N-Clean (Allergan).

Poly(vinyl alcohol) [9002-89-5] is a white to cream colored powder that softens at ca. 200 °C; it is available in a variety of viscosities and solubilities in water.

Trade names: Liquifilm, Pre-Sert (Allergan); with poly(ethylene glycol); HypoTears (CooperVision); with hydroxyethyl cellulose: NeoTears (Barnes-Hind); with polyvinylpyrrolidone: Refresh, Tears Plus (Allergan).

Contact lens products: Lens-Wet, Pre-Sert, Total, Wet-N-Soak (Allergan), Hy-Flow (Cooper-Vision); with hydroxypropyl methyl cellulose: Liquifil (Allergan), Barnes-Hind Wetting Solution, Visalens Wetting Solution; with povidone and hydroxyethyl cellulose: Barnes-Hind Wetting and Soaking Solution (Barnes-Hind); with poly(ethylene glycol) and hydroxyethyl cellulose: Lensine 5 (CooperVision).

Povidone [9003-39-8], polyvinylpyrrolidone, a pale yellow solid, M_r 10 000 – 700 000, gives colloidal solutions in water.

Trade names: With other demulcents: AdsorboTear (Alcon); Refresh, Tears Plus (Allergan).

Contact lens products: Soft Care (Barnes-Hind).

Propylene glycol [57-55-6], 1,2-propane-diol, $C_3H_8O_2$, M_r 76.09, *mp* –59 °C.

Contact lens products: Allergan Hydrocare (Allergan).

[Top of Page]

10. Miscellaneous Ophthalmic and Contact Lens Preparations

Contact lenses are broadly classified as “hard” or “soft”. *Hard lenses* are typically composed of poly(methyl methacrylate) (PMMA); they are inflexible and hydrophobic, and retain their shape when removed from the eye. *Soft (“hydrophilic”) lenses* are flexible, hydrophilic (typically with a water content of 30 – 79 %), and conform to the contour of the supporting surface. They are composed of any one of a wide variety of cross-linked polymers that form a hydrophilic gel network (e.g., polymacon, a copolymer of 2-hydroxyethyl methacrylate with 2-hydroxyethyl-2-methyl-2-propenoate) [116-118]. In addition, *“semirigid” or gas-permeable lenses* are available. These lenses are commonly made from PMMA and silicone, and are a hybrid of soft and hard lenses.

The advantages and disadvantages of each type of lens are reviewed elsewhere [116-118]. The wide range of polymers used for contact lens materials results in a broad spectrum of physicochemical interactions between the lenses, tear fluid, eye tissue, and contact lens products. For example, 20 – 30 µg of tear-fluid protein is typically deposited on a polymacon soft lens, whereas >500 µg of protein may be deposited on an etafilcon A soft lens during the same period of wear [119]. (Etafilcon A is a copolymer of 2-hydroxyethyl methacrylate, sodium methacrylate, and the trimethacrylate ester of 2-ethyl-2-hydroxymethyl-1,3-propanediol). Moreover, the compositions of the tear-fluid proteins deposited on each lens type differ: the negatively charged etafilcon A lens attracts more positively charged lysozyme than the nonionic polymacon material.

The effectiveness and cytotoxicity of the agents used for contact lens disinfection, cleaning, lubrication, wetting, etc., vary markedly with the properties of the lens material. Many factors may affect product efficacy, safety, and utility. Heat disinfection is unsatisfactory for some hydrophilic lens materials because it reduces lens life and makes deposits more difficult to remove after thermal disinfection. Chemical *disinfectants and preservatives* are described in Section Disinfectants and Preservatives. Hydrogen peroxide (3 %) is a good antimicrobial agent, but its use requires a neutralization step and has patient compliance problems. Thimerosal is also a good antimicrobial agent, but a substantial proportion of the population has become sensitized to it. Benzyl alcohol is an effective preservative but tends to irritate the eye [120]. Chlorobutanol is only a fair preservative because it has a slow kill rate, is unstable in solutions above pH 6, and is adsorbed by containers. Ethylenediaminetetraacetic acid is not an effective antimicrobial agent when used alone; it disrupts the integrity of bacterial cell walls and is used in combination with other preservatives.

Boric acid (often used as a buffering agent in ophthalmic and contact lens care solutions) and sorbic acid are preservatives with relatively low cytotoxicity, but they are not useful as lens disinfectants. Quaternary amines such as benzalkonium chloride are good disinfectants and preservatives but accumulate on negatively charged hydrophilic lenses with a high water content, causing cytotoxic responses [121-126]. Polyquad is the only quaternary amine currently in use for soft lens disinfection.

Biguanides are both potent disinfectants and good preservatives. Unfortunately, chlorhexidine has been associated with sensitivity reactions. In contrast, poly(hexamethylenebiguanide) (PHMB) has a very low frequency of adverse patient response and is safe for use with soft lens materials. Lenses disinfected with PHMB solution (0.5 ppm) can be placed directly on the eye, without the saline rinse required by most other disinfectants.

Considerable variation exists among individuals in both tear chemistry and tear deposits on contact lenses [127-132].

Most *lens cleaning agents* are used daily or weekly (see Section Contact Lens Cleaners and Rewetting Agents). Daily cleaners (e.g., macrogol esters and ethers, sodium lauryl sulfate, and block

copolymers) remove proteinaceous and lipoidal lens deposits by their surfactant action. However, daily cleaners do not completely remove protein deposits, and proteins tend to accumulate with time, serving as a possible site for microbial growth and causing eye irritation and lens clouding. Weekly cleaners are used to remove accumulated protein deposits. They are generally formulations of proteolytic enzymes (e.g., pancreatin, papain, or subtilisin-A), which cleave the protein into smaller fragments that are more readily rinsed off the lens surface.

In addition to disinfectants, preservatives, and cleaning agents, contact lens preparations may contain *lubricants*, *wetting agents*, or *viscosity adjusters* to improve lens comfort. Formulations containing such materials are listed in Chapter Dry Eye Medications (contact lens products). Contact lens solutions also contain *buffers* (e.g., borate, citrate, and phosphate) and *osmolality adjusting agents* (usually sodium chloride).

10.1. Disinfectants and Preservatives

10.1.1. *Biguanides*

See ⟶ Disinfectants.

Chlorhexidine gluconate [18472-51-0], chlorhexidine digluconate, $C_{22}H_{30}Cl_2N_{10} \cdot 2\ C_6H_{12}O_7$, M_r 897.8.

Contact lens products: Bausch & Lomb Sterile Disinfecting Solution (Bausch & Lomb); Flexcare, Flexsol (Alcon); Soft-Mate (Barnes-Hind).

Poly(hexamethylenebiguanide) hydrochloride [27083-27-8], polyaminopropyl biguanide hydrochloride $[C_8H_{17}N_5]_n \cdot HCl$. For synthesis, see [120].

Contact lens products: ReNu Multi-Purpose Solution; ReNu Saline Solution (Bausch & Lomb).

10.1.2. *Mercurial Preservatives*

Phenylmercury(II) acetate [62-38-4], $C_8H_8HgO_2$, M_r 336.8, *mp* 149 °C.

Trade name: Blinx (Barnes-Hind).

Phenylmercury(II) nitrate [8003-05-2], $C_{12}H_{11}Hg_2NO_4$, M_r 634.4, *mp* 187 – 190 °C (decomp.).

Contact lens preparation: Clean-N-Soak (Allergan).

Thimerosal [54-64-8], $C_9H_9HgNaO_2S$, M_r 404.84.

Trade names: Absorbonac, Absorbotear (Alcon); Collyrium (Wyeth); Eye Cool, 20/20 Eye Drops (Milroy); Liquifilm Forte, Prefin Z Liquifilm (Allergan); M/Rinse (Milroy); Neo Tears (Barnes-Hind); Soothe (Alcon).

Contact lens products: Adapettes (Alcon); Cleaning & Disinfecting (Allergan); Clerz (Cooper Vision); Dual-Clean (Sherman); Flex-Care, Flexsol (Alcon); Gel-Clea (Barnes-Hind); LC-65, Lens-Wet (Allergan); Pena-Vel II (Serman Labs.); Soaclens (Alcon); Soft Care, Soft Mate (Barnes-Hind); Stay Brite (Sherman); Sterile Disinfecting Solution, Sterile Lens Lubricant (Bausch & Lomb).

10.1.3. *Quaternary Ammonium Compounds*

See ⟶ Disinfectants.

See ⟶ Biocides – Quaternary Ammonium Compounds.

Benzalkonium chloride [8001-54-5] is a mixture of alkyldimethylbenzylammonium chlorides.

Trade names and contact lens products are too numerous to list.

Benzethonium chloride [121-54-0], $C_{27}H_{42}ClNO_2$, M_r 448.1, *mp* 164 – 166 °C.

Cetylpyridinium chloride [123-03-5], 1-hexadecylpyridinium chloride monohydrate, $C_{21}H_{38}ClN \cdot H_2O$, M_r 358.0, *mp* 77 – 83 °C.

Cetyltrimethylammonium bromide [505-86-2], cetrimide, is chiefly trimethyltetradecylammonium bromide together with dodecyl- and hexadecyltrimethylammonium bromides.

Trade names: Pilomann, Dexamytrex Ophtiole (Mann).

Polyquad [75345-27-6], poly[(dimethyliminio)-2-butene-1,4-diyl chloride], polyquarternium-1, polyquat.

Contact lens products: Opti-Free (Alcon).

10.1.4. *Miscellaneous Disinfectants and Preservatives*

Benzyl alcohol [100-51-6], C_7H_8O, M_r 108.1, *mp* –15.2 °C. See also ⟶ Benzyl Alcohol.

Boric acid [10043-35-3], orthoboric acid, BH_3O_3, M_r 61.84, *mp* ca. 171 °C.

Commercial products: Boric acid is used in a variety of ophthalmic and contact lens care products.

Chlorobutanol [57-15-8], 1,1,1-trichloro-2-methyl-2-propanol, $C_4H_7Cl_3O$, M_r 177.5, *mp* 97 °C.

Trade names: Gentamytrex Ophtiole (Mann); Lacril, Liquifilm Tears, Tears Plus (Allergan).

Ethylenediaminetetracetic acid [60-00-4], EDTA, $C_{10}H_{16}N_2O_8$, M_r 292.2, *mp* >300 °C. See also ⟶ Ethylenediaminetetraacetic Acid and Related Chelating Agents.

Commercial products: EDTA has widespread use in a variety of ophthalmic and contact lens care products.

Hydrogen peroxide [7722-84-1], H_2O_2, M_r 34.0. See also ⟶ Hydrogen Peroxide.

Contact lens products: OxySept (Allergan); Consept (Barnes-Hind); Quik-Sept (Bausch & Lomb); AOSept (Ciba); MiraSept (CooperVision); Murine Pure Sept (Ross).

Sorbic acid [110-44-1], 2,4-hexadienoic acid, M_r 112.12, *mp* 134.5 °C.

Ophthalmic and contact lens products: Sorbic acid is used widely as a preservative in contact lens care products.

10.2. Contact Lens Cleaners and Rewetting Agents

Most lens cleaning agents are used daily or weekly (see Section Disinfectants and Preservatives). Daily cleaners remove proteinaceous and lipoidal deposits by their surfactant action. Weekly cleaners are used to remove accumulated protein deposits.

10.2.1. *Surfactant Cleaners*

Octylphenoxypolyethoxy ethanol [9002-93-1], poly(ethylene glycol) 4-isooctylphenyl ether, $C_{34}H_{62}O_{12}$, average M_r 647.

Contact lens products: Barnes-Hind Wetting & Soaking, Soft-Mate (Barnes-Hind).

Polyoxyl 40 stearate [9004-99-3], poly(ethylene glycol) monostearate.

Contact lens product: Blink-N-Clean (Allergan).

Poly(ethylene glycol) [25322-68-3], typical lens product M_r range 190 – 420; hygroscopic, viscous liquid.

Contact lens products: Blink-N-Clean (Allergan), ReNu Effervescent Enzymatic Contact Lens Cleaner (Bausch & Lomb).

Tyloxapol [25301-02-4], 4-(1,1,3,3-tetramethylbutyl)phenol polymer with formaldehyde and ethylene oxide, tyloxypal.

Trade name: Enuclene (Alcon).

Sodium lauryl sulfate [151-21-3], sodium dodecyl sulfate, $C_{12}H_{25}NaO_4S$, M_r 288.4

Contact lens products: Lens Plus Daily Cleaner, Resolve/GP Daily Cleaner (Allergan).

Poloxamer 407 [9003-11-6], ethylene – propylene block copolymer, average M_r 4000 with 70 wt % polyethylene.

Contact lens products: Ciba Vision Lens Drops, MiraFlow Extra-Strength Cleaner (Ciba).

Poloxamine [110617-70-4], Tetronic, copolymer of ethylene oxide, propylene oxide, and tetrakis ether of ethylenediamine with propanol.

Contact lens products: ReNu Multi-Purpose Solution (Bausch & Lomb).

10.2.2. *Enzymatic Cleaners*

Pancreatin [8049-47-6] is obtained from hog pancreas and has protease, amylase, and lipase activity.

Contact lens products: Optizyme (Alcon).

Papain [9001-73-4] is derived from papaya.

Contact lens products: Allergan Enzymatic, Extenzyme (Allergan).

Subtilisin A [9014-01-1] is extracted from *Bacillus licheniformis*.

Contact lens products: ReNu Effervescent Enzymatic Contact Lens Cleaner, ReNu Thermal Enzymatic Contact Lens Cleaner (Bausch & Lomb); Ultrazyme (Allergan).

1. Introduction

Optical brighteners or, more adequately, fluorescent whitening agents (FWA) are colorless to weakly colored organic compounds that, in solution or applied to a substrate, absorb ultraviolet light (e.g., from daylight at ca. 300 – 430 nm) and reemit most of the absorbed energy as blue fluorescent light between ca. 400 and 500 nm.

In daylight optical brighteners can thus compensate for the aesthetically undesirable yellowish cast found in white industrial substrates, such as textiles, papers, or plastics. Furthermore, since a portion of the daylight spectrum not perceived by the eye is converted to visible light, the brightness of the material is enhanced to give a dazzling white.

Figure 1 illustrates the action of optical brighteners [1–3]. White substrates show a yellowish cast because their reflectance for incident visible light is lower at short wavelengths than at long ones (curve a), i.e., they absorb short-wavelength light.

Figure 1. Reflectance spectra for a textile material
a) Bleached; b) Blued; c) Treated with optical brightener [25] (c_1 absorption, c_2 fluorescence)

The first method of compensating for the yellowish cast was the use of a blue dye such

© 2005 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim
10.1002/14356007.a18_153

as ultramarine or indigo. Bluing lowers the reflectance of the sample in the long-wavelength part of the visible spectrum (curve b). As a result, the sample takes on a neutral white appearance, but at the same time it loses brightness so that it looks grayer.

Optical brighteners lower the reflectance mainly in the UV and near-visible by absorption (curve c_1); at visible wavelengths (mostly with a maximum at 435 – 440 nm), they greatly increase the reflectance through fluorescence (curve c_2). The brightener acts as a supplementary emission source.

Optical brighteners are more effective the cleaner and whiter the substrate is. In no case can they replace cleaning or bleaching.

1.1. Physical Principles

Figure 2 illustrates the processes involved in light absorption and fluorescence by optical brighteners [4–8].

Figure 2. Energy diagram of optical brighteners and transitions
A = absorption; F = fluorescence; IC = internal conversion; ISC = intersystem crossing; S = singlet state; T = triplet state

Absorption (A) of light quanta by the brightener molecules induces transitions from the singlet ground state S_0 to vibrational levels of the electronically excited singlet states S_1 and S_2. The electronic state and vibrational level reached depend on the wavelength of the absorbed light. Absorption occurs within ca. 10^{-15} s and results in a gain in energy E and a change in the electron distribution within the brightener molecule.

Brightener molecules that have been excited to a higher electronic state such as S_2 or into a higher vibrational level of S_1 relax by a nonradiative process within ca. 10^{-12} s to the vibrational ground state of S_1 (internal conversion, IC), which has a lifetime of ca. 10^{-9} s. This time is sufficient for the brightener geometry to adapt to the electron distribution in the S_1 state.

Brighteners in the S_1 state are deactivated by several routes. Fluorescence results from radiative transitions to vibrational levels of the ground state. The fluorescence emission has a lower average energy than the absorbed light (Fig. 2), i.e., fluorescence occurs at longer wavelengths than absorption (Stokes shift).

Deactivation processes competing with fluorescence are mainly nonradiative deactivation to the S_0 state (IC) and nonradiative transition to a triplet state

(intersystem crossing, ISC). Photochemical products are often formed from this triplet state. Important photochemical reactions are the $E \rightarrow Z$ isomerization of ethylene, the oxidation of pyrazoline to pyrazole, and the dimerization of coumarins (see also → Photochemistry).

The efficiency of fluorescence is measured by the quantum yield Φ:

$$\Phi = \frac{\text{Number of quanta emitted}}{\text{Number of quanta absorbed}}$$

It is determined by the relative rates of fluorescence emission and the competing processes.

In many brighteners deactivation from the S_1 state depends on the local environment. When fixed in (highly viscous) solid substrates, brighteners fluoresce with high quantum yields (Φ ca. 0.9). In (low-viscosity) solvents, such as are used before or during application of the brightener, the quantum yield is often low and the probability of formation of photoproducts is higher.

Requirements for optimally effective brighteners are as follows:

1) Brighteners should absorb as much UV light as possible and should have little inherent color. This means that the absorption maximum should lie in the 350 – 375 nm range, the extinction coefficient should be high, and the absorption band should decrease steeply near 400 nm.
2) Fluorescence should be as intense as possible and produce maximum whiteness. This

means that the quantum yield should be near 1.0. The fluorescence maximum should be between 415 and 445 nm depending on the preferred shade (violet-blue to greenish blue), the fluorescence band should decrease as rapidly as possible on the long-wavelength side.

3) The brightener distribution in the substrate should be monomolecular, even at high concentrations because aggregates of brightener molecules show dramatically lowered quantum yields and often different spectra.

Figure 3 shows typical absorption (A) and fluorescence (F) spectra for optical brighteners. Fluorescence spectra F_1 are measured in dilute solutions. On brightened substrates at the usual (i.e., higher) brightener concentrations, short-wavelength fluorescence is reabsorbed by the brightener with the result that the fluorescence band becomes narrower (F_2). A further increase in brightener concentration shifts the center of the band toward longer wavelengths corresponding to more greenish effects, up to unwanted shades.

Figure 3. Typical absorption (A) and fluorescence (F) spectra of optical brighteners [25]
F_1 = dilute solution; F_2 = applied to substrate

1.2. Molecular Structure

The chromophores of optical brighteners are π-electron systems in which $\pi - \pi*$ transitions occur. The chromophores must be rigid [5] and their conformations should differ only slightly in the electronic ground state and in the first excited state.

Brightener chromophores can be regarded as combinations of building blocks with the following numbers of π electrons:

2 π electrons:	vinylene, imino
4 π electrons:	2-pyrazolin-1,3-diyl
l6 π electrons:	1,4-phenylene, 2,5-furanediyl, 2,5-thiophenediyl, phenyl, fur-2-yl, pyrazol-4-yl, pyrazol-1-yl, 1,2,3-triazol-2-yl, 1,2,4-triazol-1-yl, 1,3,5-triazin-2-yl, 1,2,4-oxadiazol-5-yl
10 π electrons:	1,4-naphthylene, benzofuran-2-yl, benzoxazol-2-yl, benzimidazol-2-yl
12 π electrons:	4,7- coumarindiyl
14 π electrons:	naphtho[1,2-*d*]triazol-2-yl
16 π electrons:	naphthalimido, pyren-1-yl

The individual building blocks absorb at wavelengths too short for brighteners. Linking the building blocks into a system of conjugated double bonds yields chromophores that absorb at longer wavelengths.

By themselves, the building blocks with two or four π electrons (chiefly vinylene and 2-pyrazolin-1,3-diyl) absorb at very short wavelengths, but they make a significant contribution to shifting the absorption of other building blocks to longer wavelengths. They are usually combined with phenyl and phenylene groups. Examples are compounds **4**, **15**, and **53**.

In contrast, the cyclic building blocks with six π electrons give a very slight bathochromic shift. If several of these building blocks are combined, brighteners of great length and high molecular mass as well as a wide range of structures can be obtained. Examples are compounds **10** and **37**.

The absorption and fluorescence of coumarin with an exocyclic π center, naphthalimide, and pyrene are close to the favorable region for brighteners, and so only slight lengthening of these chromophore systems is necessary (**67**) or possible (**74–79**).

The optical properties of chromophores can be varied by means of substituents. Electron donors (e.g., alkyl, alkoxy, or substituted amino groups) as well as electron acceptors (e.g., cyano, alkylsulfonyl, or carbalkoxy groups) can intensify fluorescence depending on their position on the chromophore.

Substituents that have little influence on the chromophore system affect the application prop-

erties and are important for substantivity (see Chap. 4).

For reviews of optical brightener systems, see [1,3,6–21].

1.3. History of Whitening

Optical brightening was discovered in 1929 by P. Krais [22]. The whiteness of viscose rayon and semibleached flax yarn was increased by treatment with an aqueous solution of esculin (**1**) [*531-75-9*] and drying. Krais recognized that this effect was due to the strong blue fluorescence of esculin, a β-D-glucoside of 6,7-dihydroxycoumarin that is obtained by extracting horse chestnut bark. (For historical references see [23].)

The first industrial application in 1935 involved the use of sodium umbelliferone acetate [*19491-88-4*] and starch [24] and, later, chiefly β-methylumbelliferone (**2**) [*90-33-5*] [6]. As with esculin, however, these treatments lacked light- and wetfastness.

1

2

With the 1,3,5-triazin-2-yl derivatives of 4,4′-diaminostilbene-2,2′-disulfonic acid proposed by B. Wendt in 1940 [25], optical brighteners came into full-scale industrial use. In 1941, 4,4′-bis[(4-anilino-6-hydroxy-1,3,5-triazin-2-yl)amino]stilbene-2,2′-disulfonic acid disodium salt was introduced commercially under the trade name Blankophor B (**3**) [*1264-32-0*].

Subsequent development in all industrialized countries was rapid, especially during the period 1945 – 1975, leading to more than 1000 commercial products by 1989. Almost 400 compounds of distinct chemical structure or composition are registered in the Colour Index. Many of these compounds, including **3** and heterocycles such as imidazolone, dibenzothiophene-5,5′-dioxides, methine derivatives, dihydrocollidine, pyrazine, carbostyrils, pyrazolo [3,4-*b*] quinolines, and 5,6-benzocoumarins are no longer used and have been replaced by others.

3

2. Chemistry of Technical Products

This chapter deals with the most important commercial products as well as some new developments of industrial interest.

2.1. Carbocycles

The first commercial carbocyclic products were derivatives of 4,4′-diaminostilbene-2,2′-disulfonic acid, e.g., 4,4′-bis(phenylureido)stilbene-2,2′-disulfonic acid disodium salt [*2606-93-1*] (Blankophor R, commercialized in 1942) [26] and acylamino- or methoxy-substituted benzoylamino derivatives [6]. Because of their poor efficiency (i.e., yield of whiteness) and hue, these products have disappeared from the market.

Carbocyclic brighteners gained new impetus after 1959, when the trialkylphosphite-activated ethylenation process developed by Horner became available [27]. This process, which features a high yield and high selectivity for the *E* isomers needed for optical brighteners, is extremely interesting from an industrial point of view. The principal products are distyrylarenes and divinylstilbenes, which have retained their importance to the present day.

2.1.1. Distyrylbenzenes

Cyano-substituted 1,4-distyrylbenzenes (Table 1) are carbocyclic brighteners with a very

Table 1. 1,4-Distyrylbenzenes

FWA	R^1 (position)	R^2 (position)	CAS no.	Ref.
5	CN (2)	CN (3)	[*79026-03-2*]	
6	CN (2)	CN (4)	[*13001-38-2*]	[29]
7	CN (3)	CN (3)	[*36755-00-7*]	[28]
8	CN (3)	CN (4)	[*79026-02-1*]	[32]
9	CN (4)	CN (4)	[*13001-40–6*]	[28]

high whiteness and good efficiency for plastics and synthetic fibers, especially polyesters [28]. Asymmetrical compounds, mixtures of two or three different di(cyanostyryl)benzenes [29–32], or combinations with polyester brighteners differing in structure (e.g., **15**, **39**, **40**, and **42**) improve uptake and diffusion into the fiber [33] and allow the white hue to be varied over a wide range. On polyester substrates, however, the di(cyanostyryl)benzenes have only moderately good lightfastness.

For the synthesis of **4**, 2-cyanobenzyl chloride is first treated with triethyl phosphite to give 2-cyano-(1-diethylphosphonomethyl)benzene [*23973-65-1*], which reacts with terephthaldehyde in the presence of sodium methoxide to yield 1,4-bis(2-cyanostyryl)benzene (**4**) [*13001-39-3*] (Palanil Brilliant White R, 1966) [28]:

2.1.2. Distyrylbiphenyls

4,4′-Distyrylbiphenyls, discovered in 1967, can be produced in a similar way to distyrylbenzenes [34]. The reaction of 4,4′-bis(chloromethyl)biphenyl with trimethyl phosphite yields 4,4′-bis(dimethoxyphosphonomethyl)biphenyl [*27344-43-0*]. Reaction with, for example, benzaldehyde-2-sulfonic acid gives 4,4′-di(2-sulfostyryl)biphenyl disodium salt (**10**) [*27344-41-8*] (Tinopal CBS, 1972):

Anionic distyrylbiphenyls have very high efficiencies and are fairly chlorine-stable brighteners that are used for cellulosic fibers and especially for detergents (Table 2). Nonionic [35] and cationic compounds [36] have also been developed, for example [*72796-88-4*]:

$R^1 = -O-(CH_2)_2-{}^{+}N(CH_3)(C_2H_5)_2 \cdot CH_3OSO_3^-$

at the 2-position, $R^2 = H$ (see formula in Table 2).

12	OCH_3 (2)	H	[*40470-68-6*]	[35]

2.1.3. Divinylstilbenes

Polyester divinylstilbene brighteners with a very high efficiency [37] include 4,4′-di(ethoxycarbonylvinyl)stilbene (**13**) [*60683-03-6*] (Leukophor EHB, 1979), which can be obtained by the reaction of stilbene-4,4′-dicarbaldehyde with triethyl phosphonoacetate in the presence of sodium methoxide.

13

Another divinylstilbene brightener with an even higher efficacy is 4,4′-di(cyanovinyl)stilbene [*60682-87-3*] [37,38].

2.2. Triazinylaminostilbenes

1,3,5-Triazinyl derivatives of 4,4′-diaminostilbene-2,2′-disulfonic acid have been available since 1941 and remain the most important class of optical brighteners in terms of quantity. Some 75 derivatives have been put on the market [1]. In the textile industry, they find use in brightening cotton, regenerated cellulosic fibers, and polyamides. They can also be included in detergent formulations and used to brighten paper either in the pulp or in the coating.

The starting compound for all triazinylaminostilbenes is 4,4′-dinitrostilbene-2,2′-disulfonic acid [*128-42-7*], which is obtained by oxidizing 4-nitrotoluene-2-sulfonic acid with aqueous sodium hypochlorite in the presence of sodium hydroxide or, more recently, by atmospheric oxidation in an aqueous ammoniacal medium [39]. The Béchamps reduction using iron filings etched with hydrochloric acid yields 4,4′-diaminostilbene-2,2′-disulfonic acid [*81-11-8*] (DAS).

In subsequent steps, DAS is treated in acidic aqueous solution at 0 – 5 °C with cyanuric chloride dissolved in ethyl methyl ketone. The remaining chlorine atoms are then replaced by aliphatic, cycloaliphatic, or aromatic amines at 15 – 35 °C and then at ca. 60 °C. The addition of electrolytes (e.g., sodium carbonate, sodium

hydroxide) or water-soluble aprotic solvents at 90 to > 100 °C leads to the desired β crystal modification, which is nearly colorless.

Another sequence of reactions starting with DAS is needed for weakly basic amines, such as anilinesulfonic acids, and also for alcohols. These are initially reacted with cyanuric chloride, then with DAS in an aqueous medium at 40 – 50 °C. In this way the number of side reactions is substantially reduced.

Some 40 triazinylaminostilbene brighteners are currently marketed; Tables 3 and 4 respectively list the important anilino and anilinosulfonic acid representatives of bis(4,4′-triazinylamino)stilbene-2,2′-disulfonic acid. The latter can be employed over a wide pH range. All of the listed compounds are distinguished by high whitening effects, good efficiency, and adequate lightfastness, but they have only partial fastness to bleaches and none to chlorite solutions.

2.3. Stilbenyl-2*H*-triazoles

Stilbenyl-2*H*-triazoles are used as highly chlorine- and chlorite-stable brighteners for cotton and polyamides.

2.3.1. Stilbenyl-2*H*-naphtho[1,2-*d*]triazoles

The first important member of this group was 4,4′-bis(6-sulfonaphtho[1,2-*d*]triazol-2-yl)stilbene-2,2′-disulfonic acid. As the tetrasodium salt [*7426-67-7*]

(Blankophor G, 1950) [57], however, it produced a greenish-white brightening effect on cotton. Removal of one of the naphthotriazole groups from Blankophor G resulted in asymmetric compounds giving a neutral white, but at the cost of efficiency. The most important representative is the sodium salt of 4-(2*H*-naphtho[1,2-*d*]triazol-2-yl)stilbene-2-sulfonic acid(**32**) [*6416-68-8*] (Tinopal RBS, 1953) [58]. Both products are no longer marketed.

2.3.2. Bis(1,2,3-triazol-2-yl)stilbenes

Bis(1,2,3-triazol-2-yl)stilbene brighteners have high efficiencies and good lightfastness and are very resistant to chemical bleaches. They are employed as brighteners for cotton and polyamides. An example is 4,4′-bis(4-phenyl-1,2,3-triazol-2-yl)stilbene-2,2′-disulfonic acid dipotassium salt (**33**) [*52237-03-3*] (Blankophor BHC, 1970) [59].

Compound **34** is obtained by bis-hydrazone formation from hydroxyiminoacetophenone and 4,4′-dihydrazinostilbene-2,2′-disulfonic acid followed by cyclization with urea [60].

33 R = H, M = K [*52237-03-3*] [60]
34 R = SO_3Na, M = Na [*61968-72-7*] [61]

2.4. Benzoxazoles

The benzoxazole ring is especially suitable as an end group for lengthening conjugated systems that have the ability to resonate. The ring is easily synthesized and imparts good to excellent lightfastness, especially on polyester substrates. Brighteners are applied in the textile industry or added to the spinning mass. In addition, synthetic fibers such as polyamides and cellulose acetates, as well as plastics such as polyolefins, polystyrene, or poly(vinyl chloride) can be brightened with these compounds.

2.4.1. Stilbenylbenzoxazoles

Stilbenylbenzoxazoles are produced by cyclocondensation of stilbene-4-carboxylic acids with 2-aminophenols or by olefination with aromatic anils (anil synthesis); the latter requires activated tolyl compounds as reactants [62].

For example, 5,7-dimethyl-2-(4-tolyl)benzoxazole and the Schiff′s base from diphenyl-4-carbaldehyde and aniline react at 60 – 65 °C to yield 5,7-dimethyl-2-(4′-phenylstilben-4-yl)benzoxazole (**35**) [*40704-04-9*] [63] (see top of page 371).

Other stilbenylbenzoxazoles are given in Table 5. Mixtures of **35**–**37** with polyester brighteners of different structure [e.g., **4**, **6**, and **45**] are commercially available.

2.4.2. Bis(benzoxazoles)

Table 6 lists the most important bis(benzoxazole) brighteners.

In addition to the most common synthesis (the reaction of dicarboxylic acids or their chlorides with 2-aminophenols) other industrially interesting processes have been developed.

Compound **38** (Uvitex ERN, 1956) is obtained, for example, by condensing 2-amino-4-methylphenol with maleic acid to yield the diamide. Ring closure and the formation of the ethylene bridge occur on heating in a mixture of diphenyl ether and diphenyl at 135 – 155 °C in the presence of boric acid [68] (see above).

To obtain 2,5-bis(benzoxazol-2-yl)thiophene (**39**) (Uvitex EBF, 1961), two equivalents of 2-chloromethylbenzoxazole are treated with sodium sulfide, and the thiophene ring is formed with glyoxal hydrate [70]:

39

For **43** (Eastman OB 1, 1962), a new olefination reaction was discovered. 2-[4-(Chloromethyl)phenyl]benzoxazole is reacted in polar aprotic solvents with strong bases [76]:

43

2.5. Furans, Benzo[*b*]furans, and Benzimidazoles

Furans and benzo[*b*]furans are further building blocks for optical brighteners. They are used, for example, in combination with benzimidazoles and benzo[*b*]furans as biphenyl end groups.

2.5.1. Bis(benzo[*b*]furan-2-yl)biphenyls

The 4,4′-bis(benzo[*b*]furan-2-yl)biphenyls can be regarded as distyrylbiphenyls that have had their rings closed and are thus fixed in the *E* configuration. Sulfonated derivatives are described as as lightfast brighteners for polyamides and cellulosic fibers [77].

45

47

Compound **45** is produced by first treating 4,4′-bis(chloromethyl)biphenyl with salicylaldehyde to give 4,4′-biphenyldiyl-bis(methylenoxy-2-benzaldehyde). The formyl groups of this compound are converted to phenyliminomethyl groups with aniline. The double ring closure in dimethylformamide with potassium hydroxide is almost quantitative [78, 79]. The final step is sulfonation. For other syntheses, see [80].

2.5.2. Cationic Benzimidazoles

2,5-Di(1-methylbenzimidazol-2-yl)furan [*4751-43-3*] (Uvitex AT, 1967) [81], which has the ability to form salts, was one of the first cationic benzimidazole brighteners.

More recently, cationic benzimidazoles have been developed as brilliant, chlorine-fast, light-fast brighteners for polyacrylonitrile and cellulose acetate (Table 7). They are marketed in the form of cold- and heat-resistant concentrated aqueous solutions with long shelf lives.

In the synthesis of **47**, 4-methoxysalicylaldehyde is condensed with 2-chloromethyl-1-methyl-5-methylsulfonylbenzimidazole, ring closure is effected, and the product is quaternized with dimethyl sulfate [83]. To enhance water solubility, the methyl sulfate anion is converted to the acetate anion; the benzimidazole ring is first opened with sodium hydroxide and then reclosed with acetic acid because direct ion exchange is unfavorable for solubility reasons [84].

Compound **47** can also be synthesized from 6-methoxybenzo[*b*]furan-2-carboxylic acid and 2-methylamino-5-methylsulfonylaniline by cyclocondensation [83].

2.6. 1,3-Diphenyl-2-pyrazolines

Although the intense blue fluorescence of 1,3-diphenyl-2-pyrazolines had long been known [86], the usefulness of these compounds as optical brighteners was not recognized until 1949 [87]. The most valuable brighteners are the 3-(4-chlorophenyl)-1-(4-phenylsulfonic acid) derivatives because of their ready manufacturing ability, excellent optical properties, and versatility in application.

Industrial synthesis involves the reaction of β-chloro-4-chloropropiophenones with phenylhydrazines containing substituents at the 4-position, such as 4-hydrazinobenzenesulfonamide. The β-chloro-4-chloropropiophenone needed as starting material can be obtained from the Friedel–Crafts reaction of chlorobenzene with 2-chloropropionyl chloride.

1-(4-Amidosulfonylphenyl)-3-(4-chlorophenyl)-2-pyrazoline (**49**) [*2744-49-2*] (Blankophor DCB, 1961) [88] is used for the brightening of polyamides in the laundry.

Table 7. Cationic benzimidazoles

FWA	R	R^1	R^2	A^-	CAS no.	Ref.
46			H	Br^-/Cl^-	[*72829-17-5*][*74878-56-1*]	[82]
47			SO_2CH_3	CH_3COO^-	[*74878-48-1*]	[83,84]
48			H	$CH_3OSO_3^-$	[*66371-25-3*]	[85]

49

The compounds listed in Table 8 and **55** are industrially important nonionic and anionic 1,3-diphenyl-2-pyrazoline derivatives. The anionic compounds are employed to brighten polyamides but do not, however, always have adequate lightfastness. The poor wet lightfastness can be improved by the insertion of substituents in the 3-phenyl and pyrazoline rings, as in **54** and **55** [*81209-71-4*] [94]. The pyrazoline ring system is not stable against oxidative bleaches, which dehydrogenate it to the corresponding pyrazole.

The tertiary and quaternary amine salts of 1,3-diphenyl-2-pyrazoline derivatives (Table 9) are brilliant, moderately lightfast brighteners for (modified) polyacrylonitriles. Some can also be used to brighten cellulose acetate. Depending on the structure and nature of the anion, concentrated aqueous solutions with long shelf lives can be obtained; such products are needed, for example, in gel brightening.

55

The side chains R in Table 8 and $-SO_2R$ in Table 9 can be added before or after cyclocondensation, for example, by the attachment of $NaHSO_3$, amines, or alcohols to vinyl or allylsulfonyl groups.

2.7. Coumarins

Further modification of the coumarin ring system in esculin (**1**) led to the development of 7-amino-4-methylcoumarins with an *N*-alkyl group at the 7-position. The sole representative of this series still on the market is 7-diethylamino-4-methylcoumarin (**63**) [*91-44-1*] (Uvitex WGS, 1954) [101]. Despite its poor lightfastness, the good optical properties of this compound have kept it in use for the brightening of wool, cellulose acetate rayon, and polyamides. Compound **63** is produced by cy-

clocondensation of 3-diethylaminophenol with ethyl acetoacetate in the presence of zinc chloride [102].

63

Substituted 3-phenylcoumarins with methoxy [103] and triazinylamino groups [104] at the 7-position were developed later. These have been superseded in industry by the 3,7-bis(hetero)arylcoumarins [105–110].

2.8. Naphthalimides

The 4-aminonaphthalimides and their *N*-alkylated derivatives are brilliant greenish yellow fluorescent dyes (→ Fluorescent Dyes, Chap. 2.). Acylation of the amino group at the 4-position of the naphthalimide ring shifts the fluorescence toward blue [111], yielding compounds suitable for use as optical brighteners, such as 4-acetylamino-*N*-(*n*-butyl)naphthalimide [*3353-99-9*]

(Ultraphor APL, 1954) [112].

Later workers, chiefly in Japan, used naphthalimides with alkoxy substituents at the 4- or 4,5-positions and obtained brighteners with good lightfastness for polyester substrates and good chlorite fastness for polyacrylonitriles. The first commercial product was 4-methoxy-*N*-methylnaphthalimide (**64**) [*3271-05-4*]

(Mikawhite AT, 1962) [113]. Table 10 lists the most important compounds.

The naphthalimide ring system has the drawback of low effectiveness, which is mainly attributable to the low molar extinction coefficient.

The industrial synthesis of alkoxynaphthalimides begins with acenaphthene. Chlorination and subsequent oxidation with dichromate give the corresponding naphthalic acids [116], which are converted to the anhydrides on drying.

Mild reaction with methylamine, followed by reaction with sodium methoxide or sodium ethoxide, gives, e.g., **64** or **65**.

2.9. 1,3,5-Triazin-2-yl Derivatives

The sole representative of this class is 1-(4,6-dimethoxy-1,3,5-triazin-2-yl)pyrene (**67**) [*3271-22-5*]

(Fluolite XMF, 1963), which gives a bluish white brightening effect on polyester substrates; it is employed chiefly in combination with other polyester brighteners such as **38**. Compound **79** is obtained by the Friedel – Crafts reaction of cyanuric chloride with pyrene with subsequent replacement of the remaining chloro substituents with methoxy groups [117].

67

3. Commercial Forms and Brands

Commercial Forms and Formulations. Optical brighteners are formulated specifically according to structure, substrate, and mode of application. Nondusting, easily meterable forms are preferred: free-flowing granules with high crushing strength, solutions, or slurries (concentrated dispersions).

Nonionogenic optical brighteners must be as finely divided as possible so that they can be quickly and optimally distributed in apolar substrates. They are marketed as powders (e.g., for plastics or spinning masses) or as low-viscosity dispersions (e.g., for the textile industry).

Formulations are optimized with additives to control granule strength, dissolution, chemical stability, viscosity, stability on storage, or fungal growth. They can also contain toning dyes and auxiliaries to improve their efficiency in a given application.

Commercial Brands. Several thousand products with more than 100 trade names are on the market worldwide. Only a few of the most important are listed here:

Blankophor (Bayer), Hakkol (Showa Kayaku), Hostalux (Clariant), Kayaphor (Nippon Kayaku), Leukophor (Clariant), Optiblanc (3V), Photine (Hickson & Welch), Tinopal (Ciba Specialty Chemicals), Ultraphor (BASF), Uvitex (Ciba Specialty Chemicals), Whitex (Sumitomo), Belofor, Calcofluor White, Eastobright, Enkantine, Heliophor, Mikephor, Ranipal, Rylux, Viophos, and Wobital.

4. Uses

4.1. General Requirements

Optical brighteners (fluorescent whitening agents, FWAs) are used primarily in the textile, detergent, and paper industries and are also added to plastics [118]. The mode of application and performance requirements differ greatly from one substrate to another, but there are five common basic principles:

1) FWAs can only improve whiteness effectively if the substrate does not absorb too strongly in their excitation and fluorescence range. Objects with a poor "basis white", such as unbleached textiles or poorly cleaned articles, cannot be brightened to a high degree of whiteness even with high concentrations of FWAs [119].
2) FWAs only act effectively if they are monomolecularly dispersed in the substrate (see Section 1.1). This depends on the substrate, the FWA type, and the mode of application [4, 5, 120].
3) Whitening effects increase with FWA concentration up to a saturation limit. For this reason, the applied concentrations of FWA must be kept low: ca. 0.002 – 0.2 wt % relative to the substrate, or roughly one tenth of the usual concentration of dyes [4].
4) Since the use of FWAs in industrial applications should not create any problems, specific products have been developed for each type of application.
5) The required shades and fastnesses needed are also selection criteria for a suitable FWA.

4.2. Textile Industry

Brighteners can be applied to any substrate by batch or continuous processes [9, 17, 121–125]. The processes are the same as those used for dyeing (→ Textile Dyeing).

Cellulosic Fibers. Substantivity for cellulosic fibers is offered mainly by anionic FWAs, preferably with sulfonic acid groups. Brighteners such as **14**, **19**, **24**, and **26** with moderate to high affinities are suitable for batch processes. If simultaneous bleaching takes place in the same bath, the brightener must be stable with respect to bleaching chemicals such as peroxide or chlorite [126].

Continuous processes allow high throughputs of woven and knitted fabrics [127]. To achieve a level brightening effect from the beginning to the end of the process and between the center and the edges of the material, FWAs with low to moderate affinity for the fiber are used; examples of principal types are **23**, **25**, **30**, **31**, and **34**.

Brightening is often combined with a high-grade finishing process. The goods are impregnated with a synthetic resin in the padding machine, usually under strongly acidic conditions (Lewis acids can also be employed as catalysts). Brighteners must therefore meet additional stability requirements [128]; types such as **10** and **33** are especially suitable for such a process.

Polyamides. Batch brightening usually takes place in combination with reductive bleaching (dithionite). Continuous processes (padding) are followed by steam, heat, or acid treatment (acid shock) [129]. Anionic FWAs are absorbed similarly to acid dyes, or insoluble dispersion brighteners are suitable. Examples of products listed in order of increasing fastness are diaminostilbenes (**14**), (**19**); pyrazolines (**50**), (**54**); distyrylbiphenyls (**10**); and bis(triazolyl)stilbenes (**33**).

Polyacrylonitriles. An increasing proportion of the polyacrylonitrile fibers produced have a good basis white and do not require further bleaching [130, 131]. The use of FWAs that can be applied in the chlorite bleaching bath is therefore steadily declining. Suitable types include benzimidazoles such as **46**, **47**, and **48**.

If chlorite stability is not required, other less expensive, highly effective products can be used: pyrazoline derivatives such as **49** and **50** and cationic products such as **58–60** and **62**. The optical brighteners are being increasingly applied immediately after the polyacrylonitrile leaves the spinning nozzle while it is still in the gel state. Gel application has already become the dominant process in some countries (e.g., UK). Increasingly stringent fastness requirements relating to, e.g., perborate washing and exposure to light are satisfied by types **58** and **60**.

Polyesters. Dispersions of nonionogenic FWAs are suitable for hydrophobic fibers such as polyesters. Penetration into the fibers and optimal distribution are achieved by batchwise treatment at 110 – 130 °C under pressure, or at the boiling point with a "carrier" (a substance that improves diffusion of the brightener by swelling the fiber); the continuous process in the padding machine involves subsequent heat treatment at 180 – 210 °C (simultaneously resulting in good dimensional stability of the textile) [132]. The FWA molecules become oriented during thermal fixation [133]. Batch processes can be combined with bleaching, which is necessary for many polyester qualities and polyester – cellulosic mixtures.

The brighteners should be adapted to the heat treatment; they should represent an optimal compromise between diffusion into the polyester material and sublimation fastness [32, 33]. High to very high lightfastness and chlorite stability are offered by naphthalimides such as **64** and **65**; and benzoxazoles such as **35-38**, **41**, **42**, and especially **39**. Compounds such as **4 – 6**, **13**, and **67** are very effective but less stable to chlorite and light. " Boosters" (e.g., alkyl esters of stilbene dicarboxylic acids) have been suggested as a way of intensifying the action of FWAs [134].

Brighteners that sublime can be applied by transfer printing [135, 136].

Other Fibers. The main products used for cellulose acetate or triacetate fibers are pyrazoline derivatives such as **49–51**, and for wool typical polyamide brighteners.

4.3. Detergent Industry

Regular replacement of brighteners degraded during use improves the acceptance of textile articles and thus helps extend their service lives [137, 138]. Optical brighteners are therefore used in laundry detergents (→ Laundry Detergents, Chap. 3.4.5.) and are required above all for cotton fabrics [139].

Heavy-Duty Powders. Appropriate brighteners for regions with lower washing temperatures include **17** and especially **10** with its better lightfastness. FWAs such as **18** and especially **20** are used in countries where typical washing temperatures are moderate to high [140]

The preferred FWAs lend a bright, fresh, clean appearance to the detergent powder. Bleaching systems in modern detergents are effective even at low temperature, so that stringent demands are placed on FWA stability [141]. For example, triazinylaminostilbenes must be as free as possible from nonfluorescing triazine byproducts, which lead to discoloration and an unpleasant odor during storage of the detergent powder [142]. The active ingredient may also be degraded; preference is therefore given to **10**.

Heavy-Duty Liquid Detergents. The ease of incorporation and affinity of FWAs are crucial in such formulations. Heavy-duty liquid detergents can also be employed as "prespotters" that are applied in concentrated form to heavily soiled areas before the normal washing process. Bright spots can be formed, especially on colored fabrics, due to washing out of the color; they are intensified by the fluorescence of the locally high FWA concentration. For this reason, FWAs have been developed which cause less pronounced spotting that cannot be seen. The main products in use are **10** and **21** [143].

The addition of bleaches to aqueous or nonaqueous heavy-duty liquid detergents will impose even more stringent stability requirements on FWAs [144–146].

Other Laundry Products. Laundry "boosters" are bleaching systems that are added separately to the wash (→ Laundry Detergents, Chap. 4.3.2.). They contain **10** as a brightener; this compound is easy to incorporate and shows good compatibility and stability during storage [147].

Light-duty detergents contain coumarins (**63**) as brighteners for polyamide and wool. At the washing temperatures acceptable for polyesters, the FWAs cannot penetrate into the fibers. Special products containing water-soluble polymers and a lightfast brightener such as **10** have therefore been developed for use in the rinse bath after the washing of, for example, curtains [148].

4.4. Paper Industry

White paper must satisfy increasingly high standards of whiteness, which can be obtained by means of the quality and degree of bleaching of the raw materials as well as optical brightening. Brighteners can be added at three stages of papermaking: in the pulp, to the paper surface, and during coating [2, 149]. Application in the pulp has leveled off in recent years, while brightening of the paper surface and especially coating have made strong gains.

Brightening in Pulp. The brightener is added in an aqueous solution to the paper pulp during preparation in the hollander or in mixing chests. Inexpensive, highly soluble triazinylaminostilbenes such as **19**, **22**, **24**, **26**, and **30** are used. For acid-sized paper qualities, good stability toward acid and alum are necessary. There is, however, a trend toward neutral sizing.

Impregnation of Paper Web. The paper web is impregnated from one or both sides with an FWA solution that often contains other additives. In the size press, the paper is therefore brightened only on the surface, thus economizing on brightener material. Examples of products employed in this way are **24**, **26**, and **28**–**31**.

Addition to Coating. The paper is often coated with a material that contains binder and/or pigment, which usually reduces the whiteness [150]. To make up for this loss of whiteness or to provide additional brightness, FWAs such as **15**, **19**, **22**, **23**, **28**, and **29** are added to the coating.

4.5. Plastics and Synthetic Fibers

Brighteners for plastics and synthetic fibers must be "dissolved" in the material. They are added dry to the polymer powder, granulate, or chips, either before or during polymerization or else later before high-temperature forming (e.g., immediately prior to spinning in the case of synthetic fibers). Very good chemical and thermal stabilities are prerequisites for such FWAs. The brightener can also be added to the polymer solution if this is appropriate [132, 151, 152]. Low FWA concentrations are often used (e.g., 0.005 wt %) just enough to offset the yellowish cast of the material. In poly(vinyl chloride) articles, higher degrees of whiteness are achieved mainly with compounds such as **12**, **44**, and especially **40**; in polyester fibers, with products such as **43**, and especially **44**.

4.6. Other Uses

Optical brighteners are also used to enhance the whiteness of various inorganic and organic substrates, such as tripolyphosphates, carbonates, and photographic papers [152–154].

Markings visible under UV light can be made with FWAs, for example, to identify petroleum products such as fuel oil or to verify the uniform distribution of sprayed products.

Compounds such as **40** are valuable as scintillators that convert the radiation emitted by radioactive isotopes into visible light which can easily be measured [155]. Substances such as **26** are preferentially absorbed by fungi, making them easily detectable in the skin or other types of cells allowing accurate clinical diagnosis and control [156].

Some FWAs, especially **10**, are of interest as laser dyes [5, 157].

5. Analytical Methods and Whiteness Assessment

5.1. Analytical Methods

Identification. Chromatographic methods [interpretation of fluorescing spots in thin layer chromatography or of UV absorption peaks in (high performance) liquid chromatography] allow fairly rapid and certain identification of FWAs [158–166]. The same methods can be used for qualitative and quantitative characterization of the FWA purity in terms of fluorescent or nonfluorescent byproducts.

Determination in Solutions. The content of active substance is determined by photometric measurement of the extinction (absorbance) in solution (E_1^1) [158]. Both the wavelength and the height of the absorption maximum depend on the solvent. Concentrations of FWAs in application baths can be monitored quantitatively by comparative fluorescence measurements against calibrated standards [167].

When dilute FWA solutions are handled, their photosensitivity must be kept in mind. Lighting that includes UV wavelengths can lead to rearrangement (e.g., $E \rightarrow Z$) and/or degradation of the FWAs to give molecules with different spectra and chromatographic properties [18, 170].

Determination in Substrates. The FWA on a substrate can be directly determined by reflectance measurements. Alternatively, FWAs may be extracted with appropriate solvents and determined in solution; in the case of plastics, this involves dissolving the substrate [168, 169, 171, 172].

Determination in the Aquatic Environment. Identification and quantification of FWAs in sewage water and sludges as well as in surface waters and sediments require special methods of extraction and sensitive determination of photoisomers [173, 174].

5.2. Assessment of Whitening Effect

Whitening can be assessed either visually or instrumentally (by colorimetry). The quantities evaluated are the *degree of whiteness* and the *tint*. Special attention must be paid to the spectral distribution of the incident light in the UV and visible ranges, since this controls the fluorescent contribution of the brightener to the whiteness [175].

Visual assessment is performed by comparison with references in diffuse daylight [176]. White scales consisting of stages with well-defined whiteness values (e.g., the Ciba-Geigy cotton or plastic white scale) can be used [177].

For instrumental evaluation spectrophotometers are preferred; three-filter instruments can, however, also be employed. The colorimetric values obtained depend on the instrument and its instantaneous state (chiefly the sample illumination conditions) and must be controlled by suitable methods [178]. The influence of the instrument can be eliminated by conversion to the standard illumination D 65, representing daylight with a correlated color temperature of 6504 K [179]. The degree of whiteness and the tint values can then be calculated from these colorimetric data with appropriate formulas. A selection of currently used whiteness formulas can be found in [180] and [181]. For attempts at standardizing the assessment methods for white objects, see [9, 182–189].

6. Environmental Aspects

Both the toxicology and the ecotoxicology of commercial optical brighteners have been extensively studied [7, 19, 190, 191].

Acute toxicity by the oral, dermal, and inhalatory routes place these substances outside any poison class. The oral median lethal doses (LD_{50}) are generally above 2000 mg/kg. There are no indications of adverse effects as regards irritation, sensitization, or subacute toxicity. No mutagenic or teratogenic effects have been reported for the many optical brighteners so far tested. Phototoxicity and photocarcinogenicity studies on five FWAs as well as chronic rat studies with four optical brighteners produced a favorable no observable adverse effect level (NOAEL) [7]. FWAs for cotton/paper do not penetrate the skin in measurable amounts, and when fed to animals they are eliminated unchanged. Extensive work has been done to characterize aquatic toxicity and photo- and bio-

degradation. Human and environmental risk assessments of FWAs for cotton/paper show no adverse effects to human and environment [190, 191].

As industrial chemicals, fluorescent whitening agents are regulated by national laws such as the Toxic Substance Control Act in the United States and the relevant classification, packaging, and labeling directives in the European Community. For specific applications such as food packaging, the national regulatory requirements must be complied with.

Abstract

The article contains sections titled:

1. Introduction
2. Analysis of Optically Active Compounds, Determination of Optical Purity, and Assignment of Absolute Configuration
2.1. Chromatographic Analysis
2.2. Spectroscopic Analysis
3. Occurrence and Production of Optically Active Compounds
3.1. Resolution
3.2. Synthesis of Asymmetric Compounds
3.2.1. Chiral Pool Approach
3.2.2. Use of Chiral Reagents and Auxiliaries
3.2.3. Asymmetric Chemical Catalysis
3.2.4. Enzymatic Transformations

[Top of Page]

1. Introduction

The ability of certain compounds to rotate the plane of polarized light is termed optical activity. This phenomenon was first observed in 1815 by the French scientist BIOT while studying the interaction of plane polarized light with organic materials such as sugar and camphor. Thirty years later, PASTEUR demonstrated that two distinct types of crystals could be separated manually from an optically inactive salt of tartaric acid. These two forms were shown to have bulk structures that were nonsuperimposable mirror images of one another, and each type of crystal exhibited optical activity to a similar extent but in an opposite direction. The crystals that rotated the light plane to the right (clockwise) were designated (+) and termed dextrorotatory (d). Those rotating the plane of polarized light to the left (counterclockwise) were assigned the configuration (–) or levorotatory (l).

Although PASTEUR was able to separate these two optical isomers (enantiomers), the link with molecular structure did not become apparent until 1874. Following KEKULÉ's structural theory that carbon was invariably tetravalent, VAN'T HOFF reasoned that a carbon atom that is attached to four groups would have a tetrahedral geometry. Hence, if the four groups were different, the molecule would be asymmetric and nonsuperimposable on its mirror image. Molecules possessing this property of "handedness" are said to be chiral (Greek: *cheir*, hand), and molecular chirality results in the phenomenon of optical activity that is observed with a chemical compound. This may be illustrated by lactic acid.

(+)-*d*-Lactic acid [*79-33-4*] | (–)-*l*-Lactic acid [*10326-41-7*]

If a molecule has a plane or center of symmetry, it is achiral.

The two enantiomers of lactic acid, like all pairs of enantiomers in an achiral environment, have identical physical and chemical properties, except for the direction in which they rotate the plane of polarized light and the way in which they interact with other enantiomers.

A consequence of the fact that optical isomers rotate polarized light equal amounts but in opposite directions is that a 1 : 1 mixture of enantiomers is optically inactive. Such a mixture is called a racemate or a racemic mixture in the case of distinct crystalline enantiomers. Racemates comprise eutectic mixtures and behave as though they are pure compounds; thus, they exhibit physical and chemical properties that differ from those of a single enantiomer.

Optical activity is most commonly observed as a property resulting from molecular structure (in the case of solutions, gases, or liquids). However, optical activity can also be the result of a bulk phenomenon in solids such as quartz where there is a dependence on crystal structure. For the latter, the optical activity is lost on melting or dissolution. In this article, only the former type of optical activity is considered.

Specific Rotation. The optical rotation of a compound is described in quantitative terms by the specific rotation [α]. This value is obtained by using a polarimeter in which polarized light is first passed through a solution of the optically active sample and then analyzed to determine the angle through which the plane of polarization has been rotated.

The extent to which light is rotated depends on a number of variables that are discussed in more detail later. Specific rotation attempts to take account of all of these factors and provide a standardized figure for optical activity that can be used for comparison purposes. It is defined for a particular concentration of sample (*c*, expressed as grams per 100 ml) at a temperature *t* (°C) with light of wavelength λ by the equation

$$[\alpha]_{\lambda}^{t} = \frac{100\alpha}{l\,c}$$

where α is the observed rotation in degrees and *l* the sample path length in decimeters. Specific rotation is often measured by using light corresponding to the D line of sodium (λ = 589 nm) and expressed as [α] $_D$.

Representation and Nomenclature of Optically Active Compounds Many naturally occurring compounds are composed of chiral molecules and a large proportion of these compounds exist as single optical isomers. The origin of this optical activity in nature is a highly debated question, with biotic or evolutionary arguments being put forward on one hand and abiotic mechanisms such as chance or parity violations being offered as an alternative [3]. Theories to explain how a slight enantiomeric enrichment of a mixture is amplified to the exclusion of the minor component have also been propounded.

As a result of the abundance and importance of optically active compounds, various systems of nomenclature have been developed to describe absolute configuration. These are based either on the direction in which the material rotates the plane of light or on the molecular stereochemistry of the particular enantiomer being considered.

Fischer Projections. Before such systems were introduced, a convention for representing chiral molecules in two dimensions was developed by FISCHER. The Fischer projection is drawn such that the two horizontal lines represent bonds projecting out of the plane of the paper and those drawn vertically are deemed to be directed into the plane.

(+)-Lactic acid may be represented in a Fischer projection as

(+)-Lactic acid
$[\alpha]_D^{15} = +\ 3.82°(c = 10.5,\ H_2O)$

Some manipulations of these projections (e.g., 180 ° rotation) are permissible (i.e., the configuration is retained) and allow easy comparison with other molecules. However, certain transformations (e.g., interchange of any two groups) result in inversion of the absolute configuration.

D and L Notation. Lactic acid has already been described in terms of the (+)- or *d*- and (–)- or *l*-isomers, by using a system that is based solely on the direction in which each isomer rotates the plane of polarized light. Early in this century, ROSANOFF proposed a system that would relate all molecules containing asymmetric carbon atoms to either (+)- or (–)-glyceraldehyde. Molecules that could be derived from (+)-glyceraldehyde [453-17-8] were designated D and those that were correlated with (–)-glyceraldehyde [497-09-6]were denoted L. The D-(+)-isomer of glyceraldehyde was assigned, arbitrarily, the configuration

D-(+)-Glyceraldehyde
[*453-17-8*]
$[\alpha]_D^{25} = +\ 8.7°\ (c = 2.0,\ H_2O)$

Thus, by correlating an unknown asymmetric center with either (+)- or (–)-glyceraldehyde, the absolute configuration (either D or L) of a molecule was defined. It was not until 1951, when BIJVOET, by applying X-ray crystallographic techniques to sodium rubidium tartrate, showed that the stereochemical assignment of (+)-glyceraldehyde proposed by ROSANOFF was, in fact, correct [4].

The DL system is not a simple one to apply. First, molecules with identical configurations do not necessarily rotate the plane of polarized light in the same direction, e.g., (–)-glyceric acid [6000-40-4] and (+)-glyceraldehyde both have D absolute configuration. Second, some enantiomers can, by a number of steps, be related to either the D- or L-enantiomer of a known molecule, and such a situation requires an arbitrary assignment. For these reasons, this somewhat cumbersome method of assigning absolute configuration has been superseded by the Cahn – Ingold – Prelog system of nomenclature.

The Cahn – Ingold – Prelog system of nomenclature [5] assigns the absolute configuration of an asymmetric center according to the stereochemical arrangement of the four groups about that center, by application of a set of sequence rules. These rules are independent of both the magnitude and the sign of rotation. The summary of the rules given below is sufficient for assigning the vast majority of chiral compounds.

1. Substituents are ranked in order of decreasing atomic number of the atom attached directly to the central carbon.
2. If rule 1) is insufficient to assign priorities (i.e., two or more of the atoms connected to the asymmetric carbon are identical), the atomic number of the atom at the first point of difference along the substituent skeleton determines the order.
3. Multiply bonded atoms are considered as if they were an equivalent number of singly bonded atoms. Thus, a –CHO substituent is equivalent to $–CH(O)_2$.

For lactic acid, therefore, the four groups in order of decreasing priority are: –OH, $–CO_2H$, $–CH_3$, and –H.

Once the order has been determined, the molecule is oriented so that the substituent with the lowest priority is pointing away from the observer. If the direction of an arrow starting at the highest priority substituent, passing through the second, and ending at the third priority group is clockwise, the molecule is assigned *R* configuration (Latin: *rectus*, right). Conversely, the molecule has the *S* configuration (Latin: *sinister*, left) if the direction indicated by the arrow is counterclockwise.

By using (+)-lactic acid once again as the example, application of the sequence rules allows an assignment of *S* configuration to be made.

Prochirality. A carbon atom attached to four groups, two of which are the same (CX_2YZ) is achiral because it is superimposable upon its mirror image. Such a molecule is termed prochiral because replacement of one of the two identical groups X by a fourth group W results in a chiral species whose configuration depends on which enantiotopic X group is replaced. The *pro-R* substituent, when replaced by a substituent W of higher priority, affords a product with *R* configuration. Similarly, the *pro-S* substituent results in a chiral molecule with *S* configuration when replaced by W. Such considerations become important when reactions are carried out in an asymmetric environment (e.g., enzyme-mediated transformations), where often only one of the two X groups in a prochiral molecule undergoes reaction [6].

Molecules with More than One Asymmetric Center. In a molecule containing a series of *n* asymmetric centers, each center may be assigned either *R* or *S* configuration according to the sequence rules. Thus, a maximum of 2^n stereoisomers exists that form 2^{n-1} pairs of enantiomers. Stereoisomers that are not enantiomers of one another are related to each other by having some, but not all, asymmetric centers of common absolute configuration. Such isomers are termed *diastereomers*; they differ in physical and chemical properties as well as in their specific rotations. A special class of diastereomers includes those that have all but one asymmetric center with the same absolute configuration. These are termed *epimers*.

A *meso compound* is a diastereomer that is achiral by virtue of a plane of symmetry present in its molecular structure. For a molecule (e.g., tartaric acid) with two asymmetric centers, in which the three different substituents attached to these centers are common to both, only three of the maximum four (2^n, $n = 2$) stereoisomers are possible, i.e., one diastereomer comprising two enantiomers and a *meso*-diastereomer.

[87-69-4]

[147-73-9]
meso-Tartaric acid

Corresponding to enantiotopic groups in prochiral molecules, diastereotopic groups are two similar groups attached to the same carbon atom that result in diastereomers when one group is replaced. Diastereotopic groups differ in both chiral and achiral environments.

The two faces of some *trigonal species*, such as alkenes and carbonyl groups, may also be distinguished and are termed enantiotopic or diastereotopic depending on whether reaction at each face results in the formation of enantiomeric or diastereomeric products. Enantiotopic and diastereotopic faces are named by an extension of the Cahn – Ingold – Prelog system [7]. For the trigonal system XYC = Z, the double bond is treated as a single bond to a Z-C substituent. The three substituents (X,Y,Z) are then assigned priorities according to the sequence rules and if, from the direction observed, the groups are arranged in a clockwise manner, this face is termed *Re*. Conversely, if they are arranged counterclockwise, the *Si* face is observed.

Diastereoselectivity and Enantioselectivity. A reaction in which diastereomers (or enantiomers) are obtained as products is termed diastereoselective (enantioselective) if one diastereomer (enantiomer) is formed preferentially. If the starting materials and reaction environment are achiral or racemic, then the products must be optically inactive (i.e., no enantioselectivity is observed).

However, in a chiral environment or with a reagent that is chiral and nonracemic, the reaction is potentially enantioselective.

Enantiospecificity and *diastereospecificity* are terms that relate to stereospecific reactions within the context of enantiomers or diastereomers.

Other Types of Chirality. Thus far, the discussion has dealt solely with asymmetric carbon atoms as a source of chirality. However, any molecule containing an atom that has bonds to four different groups arranged tetrahedrally is chiral and can exhibit optical activity. Examples are silicon [8], germanium, zinc [9], certain transition metals, and nitrogen in quaternary salts or *N*-oxides. Pyramidal nitrogen atoms do not, in general, exhibit optical activity because racemization via inversion is rapid. However, certain aziridines, in which inversion is slow, have been resolved [10], as well as molecules incorporating a conformationally rigid asymmetric bridgehead nitrogen [11]. Phosphorus, arsenic, and antimony compounds undergo inversion more slowly and more commonly exhibit optical activity [12].

Other classes of chirality leading to optical activity are listed below.

Restricted Rotation About Single Bonds – Atropisomerism [13]. Biphenyls, with four large groups in the ortho positions of each ring, cannot freely rotate about the central bond. In such compounds the two rings are in perpendicular planes, as shown below. If W X and Y Z, the molecule lacks a plane of symmetry and is chiral, and the two enantiomers may be resolved.

Allenes. Owing to the *sp* hybridization of the central carbon atom, allenes may possess perpendicular dissymmetric planes (i.e., be chiral) if both sp^2-hybridized carbons are unsymmetrically substitued [14].

(*S*)-2-Methyl-4-phenyl-2,3-pentadienoic acid
[*36854-46-3*]
$[\alpha]_D^{25} = +149°$ ($c = 0.4$, EtOH)

Chirality Due to Helical Shape. Geometrical constraints in *trans*- cyclooctene result in two possible helical forms, which confers chirality on the molecular structure (the absolute values of the specific rotation of the following enantiomers are not identical, for an explanation see Chap. Analysis of Optically Active Compounds, Determination of Optical Purity, and Assignment of Absolute Configuration) [15].

R-(−)-*trans*-Cyclooctene
$[\alpha]_D^{25} = -458°$ (neat)

S-(+)-*trans*-Cyclooctene
$[\alpha]_D^{25} = +440°$ (neat)

Chirality Caused by Restricted Rotation of Other Types. Metallocenes (e.g., ferrocenes) with at least two different groups on one ring are chiral and are readily resolved [16].

2. Analysis of Optically Active Compounds, Determination of Optical Purity, and Assignment of Absolute Configuration

The optical purity of a compound consisting of two enantiomers (+)-A and (–)-A is commonly expressed as a percentage in terms of enantiomeric excess (% e.e.), where

$$\%\ \text{e.e.} = \frac{\%(-)-\text{A} - \%(+)-\text{A}}{\%(-)-\text{A} + \%(+)-\text{A}}$$

An indirect method for obtaining % e.e. relies on optical rotation, where [α_{max}] is the maximum rotation of the pure enantiomer.

$$\%\ \text{e.e.} = \frac{[\alpha_{\text{observed}}] \times 100}{[\alpha_{\text{max}}]}$$

Although *polarimetry* (i.e., methods of analysis based on specific rotation) and the related techniques of *optical rotatory dispersion* (ORD) and *circular dichroism* (CD) have been used extensively to determine % e.e., the limitations of these methods should be recognized. Specific rotation is concentration, temperature, and wavelength dependent, and care should be taken when comparisons are made to earlier literature. In addition, the presence in a sample of even small amounts of contaminants with high specific rotation gives misleading results.

For these reasons and because of an ever increasing demand for more reliable and precise analytical techniques, other methods for the determination of % e.e. have been developed. These are based on chromatographic and spectroscopic procedures relying on the generation of a diastereomeric interaction that is either covalent or noncovalent in nature.

2.1. Chromatographic Analysis

Reaction of a mixture of enantiomers with an optically pure reagent leads to a pair of diastereomers. For example, acylation of amines or alcohols with an optically pure carboxylic acid leads to diastereomeric amides and alcohols respectively that may be analyzed by e.g., GLC or HPLC. Optically pure amines and alcohols have also been used to derivatize a range of other types of compounds. Derivatives of this type may be used to establish absolute configuration (see Section Use of Chiral Reagents and Auxiliaries).

Alternatively, enantiomers can be analyzed via a chiral recognition mechanism by using an independent *chiral stationary*

phase. A variety of naturally occurring and synthetic chiral stationary phases are commercially available, and these materials allow the advantages of GLC and HPLC, such as speed and operational simplicity, to be employed on both analytical and preparative levels. Reverse phase supports for both HPLC and TLC are also available and are particularly important in the separation of amino acid enantiomers.

2.2. Spectroscopic Analysis

NMR spectroscopy is a flexible and reliable method for the determination of enantiomeric excess. A mixture of enantiomers may be derivatized, as described above, to give spectroscopically distinguishable diastereomers, with ^{1}H NMR being the most widely used technique.

To make the analysis straightforward, a derivative is usually chosen that contains a sharp, readily observable signal such as a methoxy moiety. An example is (*R*)- or (*S*)- α-methoxyphenylacetic acid [3966-32-3], [26164-26-1], respectively, which has been used extensively to analyze enantiomeric mixtures of both amines and alcohols. The Mosher reagent, (*R*)- or (*S*)- α-methoxy- α-(trifluoromethyl)phenylacetic acid (MTPA) [20445-31-2], [17257-71-5], respectively, is a useful alternative because it is stable toward acid- or base- catalyzed racemization, which is sometimes a problem with α-methoxyphenylacetic acid derivatives. In addition, ^{19}F NMR as well as ^{1}H NMR may be used for analysis of MTPA derivatives, and these are also suitable for analysis by GLC and HPLC.

Two other NMR methods have been used to determine the enantiomeric excess of optically active compounds. Enantiomers can often be distinguished by NMR when dissolved in a *chiral solvent*. A range of these chiral solvating agents, such as the commercially available aryltrifluoromethylmethanols and 1-arylethylamines, have found extensive application.

Optically pure variants of the well-known *lanthanide shifts reagents* provide another method of analysis. In general, the lanthanideinduced shifts are larger than those observed with chiral solvating agents, although line-broadening effects may, on occasion, present difficulties. The following are examples of the commercially available reagents, together with their commonly used abbreviations:

Tris(3-trifluoromethylhydroxy-methylene-*l*-camphorato) praseodymium(III) $Pr(tfc)_3$

Tris(3-*tert*-butylhydroxy-methylene-*d*-camphorato) europium(III) $Eu(bhmc)_3$

Tris(3-heptafluoropropyl-hydroxymethylene-*d*-camphorato)europium(III) $Eu(hfbc)_3$ or $Eu(hfc)_3$

Assignment of Absolute Configuration. A range of *spectroscopic* procedures are available for the assignment of absolute configuration to a molecule. These methods have been successfully applied on numerous occasions, usually within a related series of compounds and, although of great value, should all be employed with care. *Chemical correlation* with a structure of known configuration is another useful tool, but once again this method can be dangerously misleading for the inexperienced or unwary.

X-ray crystallographic analysis can be used to assign a configuration directly to an enantiomer, but the analysis is more commonly carried out on a diastereomeric derivative containing a stereocenter of known absolute stereochemistry; e.g., MTPA can be used to prepare diastereomeric esters and amides with chiral alcohols and amines, respectively. The problem then reduces simply to one of assigning a relative stereochemistry to the known and the unknown stereocenters, and this technique has found widespread application [17].

[Top of Page]

3. Occurrence and Production of Optically Active Compounds

Although nature frequently exhibits a high degree of symmetry in terms of general morphology, at the molecular level the natural world is highly asymmetric. Chirality is based primarily on the asymmetric carbon center, and enzymes, proteins, polysaccharides, nucleic acids, and many other basic components of plants and animals are all present in optically active

form. The implications of this on the properties of biological systems are profound. The interaction of a chiral molecule with, for example, an enzyme or receptor protein is a diasteromeric one, and a corollary of this is that two enantiomers can exhibit quite different properties. For example, (*R*)-asparagine [2058-58-4] has a bitter taste, whereas the (*S*)-isomer [70-47-3] is sweet. Clearly, if a chiral molecule is directed toward a biological target, the two enantiomers should be viewed as distinct compounds that are capable of acting in different ways. For example, (*R*)-propranolol [5051-22-9] acts as a contraceptive, whereas the (*S*)-isomer [4199-09-1] is a β-blocker. Because the potency, absorption, transport, degradation, and excretion of the two enantiomers may be quite different within the body, a racemic drug may only be "50 % pure." Although this may not be a problem, in the worst scenario the unwanted enantiomer can be highly toxic. As a consequence, the requirement for optically pure compounds is increasing, and legislation is forcing this issue in the pharmaceutical and agrochemical industries. In 1988 the FDA announced a set of guidelines addressing these stereochemical topics in relation to the submission of new drug applications. As a consequence, six of the world's top fifteen drugs are currently marketed as single enantiomers. Another factor involved is that manufacturing an unnecessary enantiomer creates waste that may be financially, as well as socially or environmentally, unacceptable.

Two basic methods exist for the synthesis of optically pure enantiomers:

1. Resolution
2. Asymmetric synthesis

3.1. Resolution

The resolution of racemates is an important source of optically pure materials. Classical resolution of a racemate (±)-A requires the use of an optically pure resolving agent, e.g., (+)-R. Interaction (which may be ionic or covalent in nature) leads to the diastereomers [(+)-A/(+)-R] and [(–)-A/(+)-R], which are separated by crystallization or chromatography. Cleavage of [(+)-A/(+)-R] gives optically pure (+)-A, which is then separated from (+)-R; the latter may be recovered. The enantiomer (–)-A is obtained analogously from diastereomer [(–)-A/(+)-R]. Optically pure carboxylic acids and amines are commonly used as resolving agents because they are readily available and their acidic – basic properties allow easy separation of the resolving agent from the enantiomer of interest. Commonly used *carboxylic acid* resolving agents include tartaric acid (and related analogues); camphorsulfonic acid, (1*R*)- [35963-20-3] and (1*S*)- [3144-16-9]; mandelic acid, (*R*)- [611-71-2] and (*S*)- [17199-29-0]; and pyroglutamic acid, (*S*)- [98-79-3] and (*R*)- [4042-36-8]. Optically pure *amines* used as resolving agents include alkaloids such as brucine [357-57-3] and cinchonidine [485-71-2], as well as ephedrine [299-42-3] and pseudoephedrine [90-82-4]. Both (*R*)- and (*S*)- α-methylbenzylamine [3886-69-9], [2627-86-3], respectively, are commercially available and are extensively employed in resolution processes.

A good example of the use of classical resolution is found in the synthesis of naproxen [22204-53-1], which is the only α-arylpropionic acid anti-inflammatory agent that is actually marketed in the optically pure *S* form. The chiral amine 1-deoxy-1-(octylamino)-D-glucitol [23323-37-3] is used as the resolving agent, and the efficiency of the process is high because the corresponding (*R*)-isomer, can be easily racemized and recycled.

Although resolution is an important source of optically pure compounds, the trial-and-error approach connected with it can be very time consuming. Considerable effort has been made in recent years to understand the factors that control the efficiency of the resolution process, and chemists are beginning to identify rational approaches to a technique that is often considered more art than science.

3.2. Synthesis of Asymmetric Compounds

The asymmetric synthesis of optically active compounds can be achieved in several ways:

1. Use of the "chiral pool"
2. Stoichiometric and catalytic methods for enantioselective synthesis
3. Enzyme-mediated processes

3.2.1. *Chiral Pool Approach*

Nature provides a wide range of optically active, although not always optically pure, materials that can be used as a starting point for asymmetric synthesis. These materials — alkaloids, terpenes, sugars, α-amino- and α-hydroxyacids — represent the so-called chiral pool.

Numerous examples exist of the use of the chiral pool approach in synthesis, many of which have important industrial applications. (*R*)-Limonene [5989-27-5], isolated from orange peel as a byproduct of the orange juice industry, provides the starting material for the commercial production of (*R*)- carvone [6485-40-1], the main constituent of spearmint flavor. The clinically important β-lactam antibiotic thienamycin [59995-64-1] is synthesized from (*S*)-aspartic acid [56-84-8], an inexpensive and readily available member of the chiral pool. Unlike many related antibiotics, thienamycin is not yet available in useful amounts by fermentation methods. However, the classical penicillins and cephalosporins that are produced by fermentation processes may themselves be regarded as components of the chiral pool, because they are used as the basis for the synthesis of a host of commercially successful drugs.

3.2.2. *Use of Chiral Reagents and Auxiliaries*

Since 1979, chiral, nonracemic reagents have been used increasingly to induce asymmetry in reaction products [18]. *Asymmetric induction*, as distinct from asymmetric catalysis (see Section Asymmetric Chemical Catalysis), involves the use of stoichiometric quantities of a chiral moiety, either a reagent or a residue attached covalently to the substrate. Removal of the reagent or auxiliary after reaction yields optically active products, and successful systems lead to chiral compounds of near 100 % optical purity. The chiral environment provided by the chiral moiety in the transition state allows the reaction to proceed solely via one of two diastereomeric pathways. At ambient temperature, a free activation energy difference $\Delta G^{\neq}$ = 12 kJ/mol between the two paths is equivalent to an enantiomeric excess in the final product of 99 %.

Thus relatively small energy differences lead to substantial stereoselectivity, and maximization of this discrimination forms the basis of asymmetric synthesis.

Some fundamental guidelines are available for the design of an efficient asymmetric synthesis:

1. The desired enantiomer should be obtained in high optical and high chemical yield.
2. The chiral auxiliary should be close to the reacting center but should not adversely affect the rate and should ideally be available in both enantiomer forms.
3. The chiral product must be readily separable from any chiral auxiliary or reagent required for synthesis.
4. The incorporation and subsequent removal of any chiral auxiliary should be chemically efficient and achieved without loss of optical activity from either the product of the reaction or the auxiliary itself.
5. If a catalytic process is used, the reagent may not have to be recovered, provided the turnover number is high.

Examples abound of the application of chiral reagents in asymmetric synthesis. Reagents based on hydridoaluminate and hydridoborate complexes have been increasingly successful in the field of asymmetric reduction since 1979. This is illustrated by the work of NOYORI [19] with (*R*)-Binal-H [70945-91-4] and MIDLAND [20] with (1*R*)-B- β-pinanyl-9-borabicyclo [3.3.1]nonane [64106-79-2].

(1*R*)-B-β-pinanyl-9-borabicyclo[3.3.1]nonane (derived from (+)-α-pinene)

Other boron-containing reagents, developed by BROWN [21], have been shown to be versatile and highly selective. Diisopinocampheylborane (Ipc_2BH) [21947-87-5] and monoisopinocampheylborane ($IpcBH_2$) [64234-27-1], both readily prepared in > 99 % e.e., are used extensively in the asymmetric reduction of a variety of functional groups, as well as the asymmetric hydroboration of a range of substituted alkenes.

Chiral amide bases that are related to the classic lithium amides (see examples below) have been used more recently for

the desymmetrization of prochiral ketones or the deracemization of racemic ketones [22], [23].

The base selects between enantiotopic protons in kinetically controlled deprotonations, and this area will develop significantly over the next few years as the mechanism by which selectivity is achieved becomes clear.

The chiral auxiliary approach to asymmetric synthesis has, over the last decade, been refined to such an extent that it now provides a versatile and often highly predictable route to a wide range of optically pure compounds. The auxiliary serves both as a chiral-inducing agent promoting the preferential formation of one configuration at the reactive center and as an internal resolving agent. This latter function allows separation of the major diastereomer and thus, on auxiliary removal, formation of optically pure products.

Because of its chemical reactivity and versatility , the carbonyl group is an especially suitable starting group, and a wide range of chiral auxiliaries (Xc) have been developed for use in this area.

The incorporation of Xc into general structures **1** and **2** allows a wide range of transformations to be carried out in a diastereoselective fashion. These include enolate-based reactions, [24-26] (alkylations and aldol condensations), 1,4-additions (organocuprates) [27], cyclopropanation [28], and Diels – Alder cycloadditions [29], [30]. In all cases the role of Xc is to confer a preferred conformation on an enolate or enone in the substrate, often associated with the formation of a metal chelate, which is accompanied by selective attack at one of the two diastereotopic faces of the reactive prochiral center or centers. The reactivity of the carbonyl group is then exploited to facilitate the removal of Xc.

The oxazolidinone chiral auxiliaries introduced by EVANS [24] serve to illustrate these principles.

Systems based on (1*S*,2*R*)-norephedrine [37577-28-9] and (*S*)-valinol [2026-48-4] provide complementary enantioselectivity in a wide range of reactions. Alkylations adjacent to the amide carbonyl proceed with good diastereoselectivity, and the chiral auxiliary may be cleaved with $LiOCH_2Ph$, for example, to yield the corresponding benzyl ester in optically pure form; the chiral auxiliary can then be recovered without loss of optical purity. Oxazolidinones of this type are also used in aldol condensations [31] and, with type **2** substrates, in Diels – Alder cycloadditions [29].

A range of other carbonyl-derived chiral auxiliaries are available for both type **1** and type **2** substrates, and selected examples are shown below [32]:

(2*S*, 3*S*)-1-Methoxy-2-amino-3-phenyl-3-hydroxypropane [*51594-34-4*]

D-2,10-Camphorsultam [*94594-90-8*]

(2*R*, 5*R*)-2,5-Dimethylpyrolidine [*62617-70-3*]

(*R*)-Acetylcarbonyl-(η^5-2,4-cyclopentadien-1-yl) triphenylphosphineiron [*36548-60-4*]

(*R*)-2-Amino-1-butanol [*5856-63-3*]

(1*R*)-8-Phenylmenthol [*65253-04-5*]

Constraining a chiral auxiliary with its associated reacting partner into a ring is often an effective means of achieving efficient asymmetric induction. This may be illustrated by the work of SCHÖLLKOPF, who has developed the use of chiral dihydropyrazines for the asymmetric synthesis of amino acids [33]:

The chiral auxiliary is an amino acid derivative (e.g., (*S*)-valine [72-18-4]), and the presence of the isopropyl residue provides the facial discrimination required for selectivity in alkylation reactions.

Chiral auxiliaries have also found application in the asymmetric synthesis of sulfoxides [34], the alkylation of both cyclic and acyclic amines [35], and 1,3-dipolar cycloaddition reactions [36].

The ideal chiral auxiliary has a low molecular mass, so that unnecessarily large amounts of material are not carried through a sequence only to be eventually removed. An obvious corollary of this is that the cost of an auxiliary should always be calculated on a mole, rather than a gram, basis. However, stoichiometric use of the auxiliary means that for large-scale industrial processes, the approach frequently becomes cumbersome. Further refinements of these methods aim to a achieve similar results under catalytic conditions (see Section Asymmetric Chemical Catalysis).

A different strategy has been developed by SEEBACH [37]. This approach does not strictly involve the use of a chiral auxiliary (which is usually recovered in its original form at the end of a sequence) but is nevertheless a very attractive

means of preparing optically pure compounds. The concept is aptly illustrated using (*R*)-3-hydroxybutanoic acid [625-72-9] as the basis of a general asymmetric synthesis of the corresponding 3-alkyl derivatives.

(*R*)-4*H*-2-(1,1-Dimethylethyl)-6-methyl-1,3-dioxin-4-one [*107289-20-3*]

91% yield
Single diastereomer

This process of “self-reproduction of chirality centers” has also been applied to the asymmetric synthesis of substituted amino acids.

3.2.3. *Asymmetric Chemical Catalysis*

A successful catalytic asymmetric transformation must satisfy a number of requirements. The reaction must be mediated or at least accelerated by the presence of the chiral catalyst to ensure that the chiral product is formed in asymmetric environment. The reactive complex must be regenerated and the product released so that further cycles can occur. Finally, the demand for high stereoselectivities is greater than in the case of stoichiometric chiral auxiliaries because the products formed are enantiomers and, therefore, not readily separable.

Arguably, the most important contribution to catalytic asymmetric synthesis in terms of versatility, predictability, and usefulness of products is the asymmetric epoxidation of allylic alcohols developed by SHARPLESS [38]. The transformation is shown in general terms below. The enantiomer of the product epoxide is determined by whether D- or L-tartrate is used and the mechanistic model developed by SHARPLESS has been found to be very reliable. To date no exception to this enantioface selection rule has been found among prochiral substrates.

Asymmetric epoxidation provides 2,3-epoxy alcohols in very high optical purity, which are themselves readily manipulated to give a wide range of functionally flexible derivatives. This catalytic process has already been used extensively by synthetic chemists and is also amenable to large-scale work.

Asymmetric hydrogenation is another area that has seen extensive development since the spectacular work by the Monsanto group in 1975. They used a reducing step, that was catalyzed by rhodium complexed to a chiral biphosphine ligand as a key step in the synthesis of L-dopa [59-92-7] [39]. Some impressive results in this area have been achieved by NOYORI [40] using ruthenium complexed to the bulky chiral ligand BINAP, (*R*)- [76189-55-4] and (*S*)- [76189-56-5] (see

below). A range of alkenes with an adjacent polar group (e.g., allylic alcohols) can be hydrogenated with very high stereoselectivity (often > 99 % e.e.) (The concentration ratio of substrate to catalyst is 10 000.)

Although a detailed mechanistic interpretation has not emerged, the scope and versatility of this catalytic system is already having a major impacts on organic synthesis.

Rhodium complexes catalyze the isomerization of *allylic amines* to *enamines*, and this reaction has found applications in asymmetric synthesis [41]. A commercial synthesis of (–)-menthol [2216-51-5] is based on the enantioselective isomerization of *N,N*-diethylgeranylamine to citronellal diethylenamine by using rhodium – BINAP.

This key step proceeds in 96 – 99 % e.e. and is responsible for a substantial quantity of the world's output of synthetic (–)-menthol.

Another application of asymmetric epoxidation or of reduction using the BINAP catalyst is in the kinetic resolution of a racemic mixture of secondary allylic alcohols [38], [42]. If one enantiomer reacts faster than the other, an optically active product is isolated. The less reactive enantiomer of the allylic alcohol is also recovered in optically active form. The success of a kinetic resolution (the optical enrichment achieved) depends on the relative rates of reaction of a pair of enantiomers. This concept is a powerful one that has also found applications in enzyme-mediated processes.

A number of other transformations have been sucessful in the field of catalytic asymmetric induction. These include the use of proline-derived catalysts in reduction and annulation processes [43], asymmetric aldol reactions mediated by a chiral gold(I) – ferrocenyl complex [44], and asymmetric catalysis in the addition of organozinc reagents to aldehydes and ketones [45]. The Diels – Alder reaction is extremely important in synthesis, and effective asymmetric catalysis for this reaction has been reported [46]. Many of the asymmetric catalyst techniques are still in their infancy and are likely to undergo major refinements in the next few years, particularly in the field of carbon – carbon bond formation.

3.2.4. *Enzymatic Transformations* (⟶ Enzymes, ⟶ Enzymes – Enzymes in Organic Synthesis; ⟶)

Enzymes are particularly valuable chiral catalysts because they can exert complete control over several stereochemical aspects in single-step transformations under mild conditions, while tolerating a wide variety of functionality. As a result of

the high specificity of enzymes, however, the success of an enzyme-mediated reaction often depends on the substrate used. Mammalian enzymes best fit the criteria of stereospecificity coupled with general applicability, whereas microbial enzymes, although more varied in type, usually have narrower structural specificities. For asymmetric synthesis the most important enzymes are oxidoreductases, hydrolases, lyases (catalyzing additions to double bonds), and less generally, ligases (e.g., aldolases). Examples of asymmetric synthesis employing enzymes are given below.

Aspartame [22839-47-0], manufactured by Monsanto, is a highly intensive sweetener (Nutrasweet). The synthesis of aspartame is based on the coupling of L-aspartic acid and L-phenylalanine derivatives, both of which are produced in cultures of microorganisms.

The specificity of enzymes, particularly hydrolases, has been exploited in the large-scale kinetic resolution of *N*-acylamino acids [47]. These enzymes are specific for the hydrolysis of the “natural” L-enantiomer, and the unreactive D-*N*-acylamino acids can then be isolated in optically active form or recycled after chemically induced racemization. Similarly, readily available hydantoinases have been used to resolve racemic hydantoins, hydrolyzing the D-isomers to yield D-amino acids, which are valuable intermediates in the production of semisynthetic penicillins and cephalosporins. The unreactive L-hydantoin can be racemized enzymatically or chemically, and recycled. Other industrial uses of enzymatic resolution include the manufacture of pure D-valine [640-68-6] in the synthesis of fluvalinate [69409-94-5], a broad-spectrum pyrethroid insecticide and (*S*)-homophenylalanine [943-73-7], a useful starting material for angiotensin converting enzyme (ACE) inhibitors.

Alcohol dehydrogenases have been widely used to catalyze the stereospecific reduction of acyclic ketones and β-ketoesters [48]. Yeast reductions are particularly convenient, and models have been suggested that successfully predict the stereoselectivity of these reactions.

Efforts are currently underway, in the field of genetic tailoring of enzymes and microorganisms, to adapt them for specific transformations. Such developments ensure that enzymatic catalysis will play an increasingly important role in the synthesis of optically active compounds.

1. Introduction

In this article optical materials are considered to be transparent solids (e.g., glasses, crystals, and polymers) from which transparent optical components such as lenses, optical flats, and prisms are fabricated. Immersion fluids and optical cements are considered to be special optical materials.

Optical materials influence the light passing through them resulting in refraction, dispersion, and absorption. Light incident on an interface of an optical material may be reflected and/or transmitted, depending on wavelength and on the directions of propagation and polarization. The direction of light passing through an interface changes as a result of refraction, which is a function of the angle of incidence. In the extreme case, light experiences total reflection. Optically anisotropic materials influence the polarization of light through birefringence.

2. Optical Properties of Optical Materials

2.1. Refraction and Dispersion

Dispersion is the result of interaction between light and the atoms in optical materials. The light excites vibrations of valence electrons (dispersion electrons). At resonance, the dispersion electrons reach a metastable excited state. Light is absorbed and its energy is transferred to the electrons. If the frequency ω of the light does not correspond to the frequency ω_{e} of the electron transition, the electrons are excited and undergo phase-shifted polarization vibrations. These dipole oscillators emit secondary waves having the same frequency as the exciting radiation but shifted in phase. The phase velocity $c_{\mathrm{n}}(\omega)$ of the light thus differs from the velocity of light in vacuum c, it depends on the difference $\omega_{\mathrm{e}}^2 - \omega^2$ and the density of the optical material. The ratio of these velocities is called the *refractive index* of the optical medium [1], [2]:

$$n(\omega) = \frac{c}{c_{\mathrm{n}}(\omega)} \tag{1}$$

If the refractive index of a material is independent of position and direction, the material is said to be *homogeneous* and *isotropic*. Homogeneous, isotropic optical materials usually have to be employed for optical components, in particular those in imaging systems. In *anisotropic* optical materials (e.g., birefringent crystals, glasses and plastics under stress), the refractive index depends on the directions of vibration and propagation of the light. The

birefringence of anisotropic materials is utilized in polarization optics. In *inhomogeneous* optical materials the refractive index varies with position.

The refractive index depends on the frequency and thus the wavelength as is approximately described by Cauchy's dispersion formula

$$n^2 = 1 + A\left(1 + \frac{B}{\lambda^2}\right) \tag{2}$$

where A and B are the refraction and dispersion constants and λ is the wavelength. Because B is small in comparison with A, the wavelength dependence of the refractive index can be neglected for estimation purposes. The phase shifts associated with the wavelength-independent part of the refractive index and the resulting effects (particularly the change in propagation direction when light passes through interfaces of optical materials) are termed *refraction*.

The frequency dependence of the refractive index is called *dispersion*. It is generally defined as the difference between the refractive indices $n(\lambda_1)$ and $n(\lambda_2)$ at two wavelengths:

$$\Delta_\lambda n = n(\lambda_1) - n(\lambda_2) \tag{4}$$

Optical materials are usually characterized by the *principal refractive index* n_e [the refractive index for the Fraunhofer line of mercury, $\lambda_e = 546.1$ nm (green)], and the *mean dispersion* $n_{F'} - n_{C'}$ [the subscripts F′ and C′ refer to

the blue ($\lambda_{F'}$= 480 nm) and red ($\lambda_{C'}$= 643.8 nm) lines of cadmium, respectively].

Another important parameter for characterizing optical materials is the *Abbe number:*

$$\nu_e = \frac{n_e - 1}{n_{F'} - n_{C'}} \tag{5}$$

Along with the principal refractive index, the Abbe number determines the location of the material in the $n-\nu$ diagram of Figure 1.

Optical materials are classified as being analogous tocrown glasses (ν_e>55) or analogous to flint glasses (ν_e<50). Optical materials with 55>ν_e>50 and n_e>1.6 are placed in the crown group (Fig. 1).

Figure 2. Variation of refractive index with wavelength for Schott BK7 glass

Most optical materials analogous to crown glasses have low refractive indices and dispersions; materials analogous to flint glasses have high refractive indices and dispersions. In conventional optical materials, the mean dispersion is approximately a linear function of the principal refractive index, as described by the law of the iron-clad line:

$$\Delta_\lambda n = Pn + Q \tag{6}$$

This formula applies to most optical glasses. In the dispersion – refractive index diagram, all optical glasses known up to 1884 lie on the iron line [3], [4].

Because the refractive index is a nonlinear function of wavelength (Eqs. 2 and 3, Fig. 2) the *partial dispersions* for stated pairs of wavelengths must be known in order to characterize dispersion in defined spectral regions. The relative partial dispersion

$$\theta = \frac{\Delta_{\lambda_p} n}{n_{F'} - n_{C'}} \tag{7}$$

is a linear function of the Abbe number for most optical glasses:

$$\theta_n = a + b\nu \tag{8}$$

The correction of the secondary spectrum calls for optical materials with relative partial dispersions that differ greatly from the values predicted by the normal straight line (Eq. 8, see Section 3.3). Materials with large anomalous partial dispersions include fluorspar, barium fluoride, potassium alum, and the dense fluorophosphate crown glasses.

2.2. Interfacial Properties

When light travels from one medium to another it is split into a reflected part I″ and a transmitted part I′. In accordance with Fresnel's formulas [2], reflectance and transmittance depend on the wavelength, the polarization and incident propagation directions, and the refractive indices of the optical material and the surroundings. The intensity ratios are called the *spectral reflectance*

$$\varrho(\lambda) = \frac{I''}{I_o} \tag{10}$$

and the *spectral transmittance*

$$\tau_F(\lambda) = \frac{I'}{I_o} \tag{11}$$

where I_o is the intensity of the incident light (the subscript F stands for Fresnel). In the case of normal (i.e., 90°) incidence, the spectral reflectance and transmittance are independent of polarization:

$$\varrho\left(\lambda, \frac{\pi}{2}\right) = \left(\frac{n' - n}{n' + n}\right)^2 \tag{10a}$$

$$\tau_F\left(\lambda, \frac{\pi}{2}\right) = \frac{4n'n}{(n' + n)^2} \tag{11a}$$

where n and n' are the refractive indices in front of and behind the interface.

The reflected light is described by the *law of reflection*

$$\varepsilon'' = -\varepsilon \tag{12}$$

which states that the angle of incidence ε equals the angle of reflection ε'', both angles being measured from the normal to the interface

Figure 3. Change in direction of propagation due to change in phase velocity for light obliquely incident on an interface (Snell's law)
c_n and c'_n phase velocities in the two media; ε = angle of incidence; ε' = angle of refraction; ε'' = angle of reflection

(Fig. 3). The incident ray, the reflected ray, and the normal lie in the same plane.

The light passing through the interface is refracted. The difference in phase velocity on either side of the interface leads to a change in the direction of propagation for oblique incidence, as described by *Snell's law*

$$n' \sin\varepsilon' = n \sin\varepsilon \tag{13}$$

where ε' is the angle of refraction. The refracted ray lies in the incidence plane (the plane containing the incident and reflected rays and the surface normal). In optically denser media ($n' > n$), the ray is refracted toward the surface normal ($\varepsilon' < \varepsilon$); in optically less dense media ($n' < n$), $\varepsilon' > \varepsilon$ (Fig. 4 A). At the critical angle ε_g the angle of refraction is 90° ($\varepsilon' = 90°$), i.e., it propagates at a grazing angle in the interface (Fig. 4 B). If the incidence angle exceeds the critical angle (Fig. 4 C)

$$\varepsilon_g = \arcsin \frac{n'}{n} \tag{14}$$

then total reflection occurs (Fig. 4 C).

Total reflection is utilized for light deflection in prisms, and mirrors → Mirrors; refraction forms the basis for optical imaging.

2.3. Birefringence

In anisotropic optical media the lattice structure may lack central symmetry (e.g., in noncubic crystals) or there may be internal and external stresses. As a result the phase velocity and thus the refractive index depend on the polarization and propagation directions of the light. A light wave incident on an optically anisotropic material is generally split into two orthogonally polarized partial waves, which propagate at different phase velocities. In the case of oblique incidence, the two partial waves have different angles of refraction, and thus different refractive indices. This phenomenon is called *birefringence* or *double refraction.*

Birefringence is only absent in defined directions termed the optical (crystal) axes. Tetragonal, hexagonal, and rhombohedral crystals (e.g.,

Figure 4. Reflection of obliquely incident light at varying angles of incidence (ε) for two media with refractive indices n and n' ($n > n'$)
A) $\varepsilon < \varepsilon_g$; B) $\varepsilon = \varepsilon_g$; C) Total reflection $\varepsilon > \varepsilon_g$
ε_g = critical angle; ε' = angle of refraction; ε'' = angle of reflection

quartz and calcite) are optically uniaxial; monoclinic, triclinic, and rhombic crystals are optically biaxial. Optically uniaxial crystals are generally of importance in polarization optics.

Any plane that corresponds to an optical axis of a crystal is termed the *principal section (plane)* of the crystal. In optically uniaxial crystals, the electric field of the extraordinary ray vibrates in the principal section. The extraordinary ray has a direction-dependent phase velocity that depends on the direction-dependent extraordinary refractive index $n_{eo}(\varphi)$. The electric field vibration of the ordinary ray is orthogonal to the principal plane section. The phase velocity and the ordinary refractive index n_o of the ordinary ray are independent of direction.

The extraordinary refractive index $n_{eo}(\varphi)$ has an extreme value $n_{eo}(\pi/2)$ perpendicular to the optical axis of the crystal. In the case of negative birefringence (as in calcite with n_o=1.662 and $n_{eo}(\pi/2)$=1.488), this extreme value is a minimum. In the case of positive birefringence (e.g., quartz, n_o=1.546, $n_{eo}(\pi/2)$=1.555), it is a maximum. Birefringent materials are used in double-image polarizing prisms and in delay or phase plates. In prism-type polarizers, such as the Nicol prism (Fig. 5 A), linearly polarized light is obtained from unpolarized light by using total reflection to trap the ordinary ray. In polarization-type beam splitters, such as the Wollaston prism (Fig. 5 B), the two orthogonally polarized beams leave the device in different directions. Delay or phase plates are used to produce elliptically and circularly polarized light. They consist of birefringent plates made of uniaxial quartz or of biaxial mica or gypsum in which the parallel faces lie parallel to a principal section of the crystal. If the light is normally incident, the extraordinary and ordinary rays differ only in the distance traveled. The path difference $d\,[n_{eo}(\pi/2) - n_o]$ depends on the thickness d of the plate and the maximum birefringence $n_{eo}(\pi/2) - n_o$. In a $\lambda/4$ (quarter-wave) plate, the path difference is $(2m+1)\,\lambda/4$ and the phase difference is $(2m+1)\,\pi/2$. The plate thickness is given by

$$d = \frac{(2m+1)}{n_{eo}\left(\frac{\pi}{2}\right) - n_o} \cdot \frac{\lambda}{4} \tag{15}$$

with $m = 0, 1, 2, \ldots$

2.4. Absorption and Scattering

An optical material only transmits light in certain portions of the spectrum. Even in these "spectral windows," some of the light entering the material is lost. Absorption of light depends on the nature of the atoms in the material, their bonding, the wavelength of the light, and the path length d traveled by the light.

The ratio of absorbed intensity $\Delta I'_{\mathrm{A}}$ to incident intensity I_0 is called the *spectral absorptance:*

$$\alpha(\lambda) = \frac{\Delta I'_{\mathrm{A}}}{I_0} \tag{16}$$

The absorbed intensity $\Delta I'_{\mathrm{A}}$ divided by the intensity I' passing through the boundary of the material (adjusted for Fresnel reflection losses I'') is called the *internal spectral absorptance*:

$$\alpha_{\mathrm{i}}(\lambda) = \frac{\Delta I'_{\mathrm{A}}}{I'} = \frac{\alpha(\lambda)}{1-\varrho} \tag{17}$$

The *internal spectral transmittance* is given by

$$\tau_{\mathrm{i}}(\lambda) = 1-\alpha_{\mathrm{i}}(\lambda) = \frac{I'-\Delta I'_{\mathrm{A}}}{I'} \tag{18}$$

In homogeneous media, it is described by the *Bouguer–Lambert law*

$$\tau_{\mathrm{i}}(\lambda) = \mathrm{e}^{-Kd} \tag{18a}$$

which states that the absorption intensity increases with the thickness d of the material. The absorption coefficient

$$K = \frac{4\pi}{\lambda} n\kappa \tag{19}$$

is a function of the absorption constant $n\,\kappa$ and thus of the absorption index κ. The absorption constant is the imaginary part of the complex refractive index

$$\tilde{n} = n(1-i\kappa) \tag{20}$$

of an absorbing medium, where i is the imaginary unit. The reciprocal of the absorption coefficient gives the mean range, which is the path length after which the intensity is reduced by a factor of (1−1/e).

A reflection factor can be defined which describes transmission through both bounding surfaces taking into consideration weak multiple reflection and absorption:

$$\frac{2n}{n^2+1}$$

The formula is only strictly valid for normal incidence. The *spectral transmission factor* is defined as

$$\tau(\lambda) = \frac{2n}{n^2+1} \cdot \tau_{\mathrm{i}}(\lambda) \tag{21}$$

It describes the ratio of light intensity leaving an optical material to that entering the material.

If *scattering losses* also occur in the material, absorption and scattering are added together and referred to as *extinction* or *optical density*. The sum of the absorption coefficient and the analogous scattering coefficient K_{S} is the extinction coefficient:

$$K_{\mathrm{E}} = K + K_{\mathrm{S}} \tag{22}$$

Similarly to Equations (18 a) and (19), the extinction, extinction constant, and extinction index can be defined in terms of K_{E}.

Nonselective internal transmittance is generally desired in optical materials, but no material has this property [5]. Most of the energetically more favorable crystals (e.g., LiF, CaF_2, BaF_2) have their ultraviolet absorption limit at a shorter wavelength than the metastable glasses (Fig. 6) [5].

The dependence of absorption on the propagation and polarization directions, observed in colored birefringent crystals, is called *pleochroism.* Optically uniaxial crystals (e.g., tourmaline

Figure 6. Ultraviolet internal spectral transmission τ_i of optical glasses (Schott, Mainz) and crystals for a 5 mm path (λ = wavelength)

and penninite) exhibit *dichroism* with different absorption constants for two orthogonal polarization directions. By choosing an appropriate material thickness one component can be attenuated to such a degree that the crystalline plate can be used as a dichroic polarizer. Polarizers can also be fabricated by dyeing polyvinyl films.

3. Effect of Optical Material on Imaging

Refraction of light at appropriately shaped boundaries of optical materials is the most important principle employed in conventional optics. It is exploited in lenses and lens systems which produce an optical image by focusing the light from the individual points of an object at the respective conjugate image points.

Lenses are generally cylindrical bodies with spherical refracting surfaces at which light is deflected in accordance with Snell's law (Eq. 13). A lens is characterized in terms of the refractive index n, its central thickness d, and the radii r_1 and r_2 of the refracting surfaces. A radius is positive if the center of curvature C is to the right of the vertex of the corresponding surface, or negative if the center is to the left of the vertex. The line joining the centers of curvature C_1 and C_2 is the optical axis of the lens, which should also be the axis of the cylinder bounding the lens. In drawings, only the meridional section containing the optical axis is shown (Fig. 7).

The action of a lens can be described in a zero-order approximation by a model of two principal planes orthogonal to the optical axis. The lens images these planes on one another at a scale of 1 : 1. Ray deflection is assumed to take place at these planes. The principal points H and H′ lie at the intersection of the optical axis with the principal planes. The distances between the principal points and the points S_1 and S_2 at which the lens surfaces intersect the optical axis are given by

$$s_{H'} = S_2H' = \frac{r_2 d}{n(r_1 - r_2) - d(n-1)} \tag{23a}$$

$$s_H = S_1H = \frac{r_1 d}{n(r_1 - r_2) - d(n-1)} \tag{23b}$$

The light-deflecting action of a lens is determined by the focal length f'. Parallel bundles of rays are approximately focused on the back (image) focal plane, at a distance f' from the back principal plane. The focal point F′ is the point at which the optical axis meets the focal plane. The reciprocal of the focal length is the focal power or strength of the lens:

Figure 7. Design parameters, principal points, and focal points of a spherical lens
C = center of curvature; d = central thickness; $\overline{f}$ = front focal length; f' = back focal length; $\overline{\mathrm{F}}$ and F′ = front and back focal points; H and H′ = first and second principle points; r = radius of curvature; $s_{\overline{\mathrm{F}}}$ = front focal distance (from the front lens surface to the first principle focus); $s'_{\mathrm{F}'}$ = back focal distance (from the back lens surface to the back principle focus)

$$D' = \frac{1}{f'} = (n-1)\left(\frac{1}{r_1} - \frac{1}{r_2} + \frac{n-1}{n}\cdot\frac{d}{r_1 r_2}\right) \tag{24}$$

which serves as a measure of the deflection of a ray. For thin lenses, the third term in the second set of parentheses in Equation (24) can be neglected [2]:

$$D' = (n-1)\left(\frac{1}{r_1} - \frac{1}{r_2}\right) \tag{24a}$$

The refractive power can be expressed in terms of two distances a and a'; a is the distance from the object to the front or object principal plane; a' is the distance from the image plane to the back principal plane. The Gaussian lens formula

$$\frac{1}{a'} - \frac{1}{a} = D' \tag{25}$$

is only strictly valid for small incidence angles at the refracting surfaces: $\varepsilon \approx \sin\varepsilon \approx \tan\varepsilon$ (i.e., for rays in the immediate vicinity of the optical axis). Outside this paraxial region, the paths of rays through the lens do not match the paths predicted by Equation (25) (Fig. 8 A). Such aberrations prevent the ideal convergence of ray bundles at the image points [2]. They can be minimized by making the refracting surfaces flatter to decrease the angle of incidence.

3.1. Effect of Refractive Index on Optical Imaging

The decrease in focal power that occurs in less strongly curved lenses (Eq. 24 a) can be compensated by the use of highly refractive materials. Such highly refractive lenses are thinner and have smaller aberrations than lenses made of normally refractive material (Fig. 8 B) [5]. To achieve a given correction without a highly refractive material, several less strongly curved lenses with the same total focal power must be combined (Fig. 8 C). The use of highly refractive material allows the number of lens elements in an optical system to be reduced; this is particularly important for photographic objectives.

Lenses with a high focal power and a large diameter can be made only from high-refraction material, since otherwise the strongly curved surfaces required by Equation (24 a) can lead to total reflection [5].

Combinations of high- and low-refraction materials used for correction purposes are especially effective in cemented and wringing components because they permit the use of less strongly curved mating surfaces. Low-index optical materials are needed for weak diverging (concave) lenses that are used in optical systems because their strongly overcorrecting action (in relation to the focal power) can offset the aberrations produced by converging (convex) lenses.

Figure 8. Aberrations of (A) a strongly curved lens made of a normally refractive material ($n = 1.5$), (B) a less strongly curved lens made of a highly refractive material ($n \approx 10$), and (C) a system consisting of several less strongly curved lenses made of a normally refractive material
b' = curvature of field; $\Delta y'$ = transverse aberration

3.2. Effect of Dispersion on Optical Imaging

Since the focal power of a lens depends on the refractive index (Eq. 24) and the refractive index is wavelength dependent, the focal lengths and the position of the focal plane or image plane also depend on wavelength. These variations with wavelength are referred to as *chromatic aberrations* [2].

The chromatic aberration of the focal length $\Delta_\lambda f'$ produces a chromatic variation of the image size $\Delta_\lambda y'$. This is called *transverse chromatic aberration* or color magnification error (Fig. 9).

The locations of the principal planes also depend on the refractive index and thus the dispersion (Eqs. 23 a, 23 b). With thick lenses, a distinction must be made between the chromatic aberration of the focal length $\Delta_\lambda f'$ and the chromatic variation of the paraxial image position $\Delta_\lambda s'$ (Fig. 9 A), also called *longitudinal chromatic aberration.* The latter term refers to the wavelength dependence of the image-plane position; it represents the distance between the image planes for the two extreme wavelengths of a useful spectral region $\Delta\lambda$. The longitudinal chromatic aberration of a thin simple lens is given by Equation (26).

$$\Delta_\lambda s' = \frac{-f'}{\nu} \tag{26}$$

It can be corrected for two wavelengths by cementing together a converging lens with focal length $f'_C > 0$, made of a crown-glass analogue (Abbe number $\nu_C > 55$) and a diverging lens with focal length

$$f'_F = -\frac{\nu_C}{\nu_F} f' = \left(1 - \frac{\nu_C}{\nu_F}\right) f' \tag{27}$$

made of a flint-glass analogue (Abbe number $\nu_F < 50$). Here f' is the overall focal length of the resulting achromat (Fig. 9 B).

Figure 9. Chromatic aberrations of (A) a single lens, (B) an achromat, and (C) a trichromat, shown as ray diagrams
$\Delta_\lambda y'$ = transverse chromatic aberration; $\Delta_\lambda s'$ = longitudinal chromatic aberration; $\Delta_s s'$ = secondary spectrum; λ = wavelength

In order to correct the monochromatic aberrations of the achromat, in particular the spherical aberration (Fig. 10), f'_C must be much greater than $-f'_F$. This means that the Abbe numbers must differ by at least 25. The *spherical aberration* (also called aperture aberration) denotes the difference between the point where the ray actually passes through the image plane and the ideal image point. This difference increases with the incidence height of the ray on the lens. A diffuse circle is produced instead of the ideal image point. Because the spherical aberrations of a converging lens and a diverging lens are opposite in sense, they can largely compensate one another when the two lenses are cemented together. Such a lens unit, called an *achromat* (or achromatic lens) consists of a low-index crown-glass analogue with low dispersion and a high-index flint-glass analogue with high dispersion; it corrects both spherical aberration and longitudinal chromatic aberration. The lens still has a residual error called *spherochromatism*, which is the chromatic variation of the spherical aberration (Fig. 11). This can be corrected with a new achromat consisting of a high-index material with low dispersion and a low-index material with high dispersion. Since, however, the new achromat also has a spherical aberration, the old achromat is combined with the new achromat to correct both the spherical aberration and spherochromatism. Combinations of this type are called *anastigmats* [2].

Figure 10. Spherical aberration

3.3. Effect of Partial Dispersion on Optical Imaging

The longitudinal chromatic aberration of an achromat can be corrected only for two wavelengths (Fig. 9 B). This type of cemented lens does not offer achromatic, but rather dichromatic correction.

The residual longitudinal chromatic aberration of such a dichromat is called the *secondary spectrum*

$$\Delta_S s' = -\frac{\theta_C - \theta_F}{\nu_C - \nu_F} f' \tag{28}$$

which depends on the difference between the relative partial dispersions (Eq. 7) of the two materials. As a result of the linear relationship given in Equation (8), equal relative partial dispersions (as required for correction of the secondary spectrum) cannot generally be obtained at the largest possible difference in Abbe numbers ($\nu_C - \nu_F > 25$). For achromats made of optical media that lie on the normal straight line defined in Equation (8), the secondary spectrum is therefore roughly constant:

$$\Delta_S s' = -b f' \tag{28a}$$

The secondary spectrum can be corrected for by supplementing the achromat shown in Figure 9 B with a lens made of an optical medium that exhibits anomalous partial dispersion (i.e., materials such as CaF_2, BaF_2, dense fluorophosphate crowns, or extralight flint glasses that do not obey Eq. 8). Systems of this type are called *trichromats* (Fig. 9 C). If they also correct for spherochromatism, they are called *apochromats* [2].

3.4. Effect of Transmittance on Optical Imaging

Since the resolving power of an optical system is inversely proportional to the wavelength, high resolution dictates the use of short wavelengths. In other words, it is necessary to use optical materials having high transmittance in the UV and DUV (deep ultraviolet). Optical storage, astronomy, microscopy, microlithography, and spectroscopy require internal transmittance of at least 50 % through a 10 mm thickness of material [5].

The UV absorption of optical glasses is roughly proportional to the refractive index [5]. Optical glasses used in UV microlithography therefore have a refractive index below 1.65. For wavelengths shorter than 400 nm, only silicate

Figure 11. Spherochromatism
The subscripts F′ and C′ refer to the blue ($\lambda_{F'}$ = 480 nm) and red ($\lambda_{C'}$ = 643.8 nm) lines of cadmium, respectively.

glass and isotropic crystals such as CaF_2, BaF_2, spinel, and MgO can be used; weakly birefringent sapphire can also be employed under certain conditions.

4. Optical Glasses

For a detailed description of glass, see →Glass.

Glasses are the most important optical materials because their optical properties vary over wide ranges (Fig. 1). Refractive indices lie between about 1.3 and 2.2. The homogeneity and isotropy of the refractive index are of vital importance. Inhomogeneity and anisotropy give rise to phase shifts that cause undesired noise and distort the image structure.

The principal defect in small-diameter lenses is the occurrence of cords or striae which deform the wavefronts in large pupil areas. Suppression of cords is particularly important for the titanium flints and fluor crowns used in microscopic and photographic objectives. The permissible wave aberrations due to cords range between $\lambda/12$ and $\lambda/100$ [6].

For photolithographic objectives with their large lens diameter, interference due to large area inhomogeneities with low refractive-index gradients predominate. The variations in the refractive index in these inhomogeneities must be kept below 2×10^{-7} to 3×10^{-7} in lens blanks depending on lens diameter and thickness.

In the case of stress birefringence, tolerances are between 15 and 0.1 nm/cm (for polarization microscopy) [5].

Rational production methods demand that the refractive index should be constant to $\pm10^{-4}$ for photographic and microscope optics and to $\pm10^{-5}$ for photolithographic objectives. Microheterogeneities and bubbles act as scattering centers and interfere above all in coherent optical imaging, integrated optics, and fiber-optic communications.

Because the amorphous glassy state is metastable due to its high free energy, lower-energy photons (i.e., longer wavelengths) are needed for electron excitation than in the ordered, lower-energy, more stable crystalline state. Accordingly, the UV absorption edge of glasses occurs at a longer wavelength than that

of crystals (Fig. 6). Silicate and fluorophosphate glasses have a high UV transparency (Fig. 6).

In contrast to pure silicate glass, multicomponent glasses with their higher refractive indices (e.g., BK10, BaK5) do not have internal transmittance values of unity, even though there is no interaction between light and network components in the visible region. This is because even traces of iron, lead, manganese, cobalt, nickel, chromium, titanium, and cerium lead to selective transmission losses and a further shift of the UV absorption edge toward longer wavelengths [5].

The transmittance of high-index dense flint (SF) and dense barium flint (BaSF) glasses is unfavorable because the UV absorption edge is shifted further toward long wavelengths. Such glasses tend to take on a yellow cast with increasing refractive index, leading to shifts in color locus.

Good chemical stability is required for both the use and the processing of optical glasses. Acid attack (due to sweat from the hands, atmospheric CO_2 and SO_2, etc.) leads to exchange of hydrogen ions with network modifiers and the formation of low-index silica gel layers. These layers may result in formation of spots or even disintegration of the glass.

Flowing water has a less drastic action than acids, because the water-soluble alkaline products formed in the primary reactions are removed before the secondary reaction products can attack the glass surface. When a glass is exposed to atmospheric humidity, the primary reaction products remain on the surface and dissolve the network. The glass weathers and layers of material are lost.

Optical glasses are characterized by the principal refractive index n_e, the Abbe number (Eq. 5), and the type designation (e.g., BK 7 for a borosilicate crown). Types of glass are classified by their position in the n–ν diagram. The nomenclature is based on that devised by Otto Schott. Glasses are divided into the less dispersive crown glasses ($\nu_e > 55$) and the more dispersive flint glasses ($\nu_e < 50$). The range $55 > \nu_e > 50$ includes the barium light flints, crown flints, some extralight flints, and crown glasses.

Extremely low refractive indices, down to about 1.3, are found in the beryllium fluoride crowns (BeFK) [7], but these are not approved for use in most European countries because of the high toxicity of beryllium. The dense (heavy) fluorophosphate crowns (FPSK) [8], [9] have low refractive indices, high anomalous partial dispersions, and good UV transmittance. They are made by melting the phosphates and fluorides of the alkaline earth and rare-earth metals, but their strong crystallization tendency and their poor weathering resistance make them difficult to work with. The fluorocrowns (FK) have low refractive index and low density; they contain fluorine in place of oxygen in a glass matrix consisting of the oxides of light elements. The low-index, high-dispersion titanium flints (TiF) and dense titanium flints (TiSF) are obtained by incorporating fluorine in lead flint glasses. Borosilicate crowns (BK) and zinc crowns (ZK) contain up to 20 % B_2O_3 and ZnO, respectively, in place of SiO_2. The barium crowns (BaK), which contain nearly 30 % BaO, have higher refractive indices and dispersions than the light barium crowns (BaLK), which contain a maximum of 10 % BaO. If the BaO content is brought close to 50 %, dense crowns (SK) are obtained; if PbO and TiO_2 are added, the more highly refractive and dispersive extra-dense (very heavy) crowns (SSK) result. The highest refractive indices in the crown-glass region belong to the lanthanum crowns (LaK) and dense lanthanum crowns (LaSK). The high-index lanthanum flints (LaF) and extra-dense lanthanum flints (LaSF) contain oxides of lanthanum, lead and titanium. Flint glasses of moderate dispersion and index follow (listed in order of decreasing BaO and PbO contents): dense barium flints (BaSF), barium flints (BaF), flints (F), light flints (LF), and extra-light (very light) flints (LLF). The highest refractive indices and dispersions belong to the dense flints (SF), containing up to 70 % lead oxide and titanium oxide. They are exceeded only by the not-yet-commercialized telluride glasses, some of which have a strong yellow cast. Short flints, contain ≤ 20 % Sb_2O_3, lower dispersion in the blue, and thus show anomalous partial dispersion.

Optical glasses are supplied in several forms: as slabs with polished inspection surfaces, uncut or cut blocks with two polished surfaces, profile rods with uncut lateral surfaces, round blanks made by gobbing, and preformed molded or cut blanks. The maximum within-melt variation in refractive index for standard quality is $\pm 10^{-4}$, for precision quality glass, $\pm 5 \times 10^{-6}$.

High-volume optical glasses are produced in continuous melters. Molded or gobbed blanks are taken or the molten glass is continuously cast into rods.

5. Colored or Filter Glasses

Colored or filter glasses are employed for selective absorption. For example, a yellow filter intercepty the complementary blue portion of the spectrum. Glass can be colored with ions of heavy metals (e.g., Cu, Co, Ni, Fe, Cr, and Mn) or rare earths (e.g., Nd and Pr) or with colloidal particles of sulfides (e.g., CdS), selenides (e.g., CdSe), or metals (e.g., Cu, Ag, Au, or Se). The composition of the base glass is also important. Copper ions, for example, produce a blue color in conventional potassium – calcium glasses but a blue-green in borosilicate glasses.

The transition from transmission to absorption, especially in ion-colored glasses (Fig. 12 A), generally covers a wider range of wavelengths then in interference filters. Tempered glasses, in which the colored colloids listed above are precipitated after heat treatment, show a steep curve between the short-wavelength absorption region and the long-wavelength transmission region (Fig. 12 B). A steep flank cannot be obtained in the long-wavelength absorption region of filter glasses, neither can narrow spectral bands be filtered out (Fig. 12 C). The gray, compensating or neutral glass filter attenuates light fairly uniformly throughout the visible region (Fig. 12 D).

6. Optical Crystals

Optical crystals have several advantages over optical glasses: better transmittance in the UV and IR, extreme refractive indices and dispersions, and high anomalous partial dispersions [10]. The more stable crystal structure with its lower-energy configuration shifts the UV absorption edge to shorter wavelengths than those found for the metastable, amorphous glassy state (Fig. 6) [5].

Many crystals offer excellent wideband transmission, from UV to IR; this is important chiefly in spectroscopy (e.g., for filters and windows) [11], [12]. Pure oxide crystals such as quartz, magnesium oxide, corundum, spinel ($MgAl_2O_4$), GGG ($Gd_3Ga_5O_{12}$), and undoped YAG (yttrium aluminum garnet) have outstanding transparency into the deep ultraviolet, as do pure fluoride crystals such as LiF, NaF, CaF_2, and MgF_2. This is significant for the use of (especially) BaF_2, CaF_2, and undoped YAG for deep ultraviolet microprojection lithography between 300 and 200 nm.

Typical IR crystals include Si, Ge, NaCl, NaF, KBr, KSR5 (TlBrI), CdTe, ZnSe, ZnS, and GaAs; CsI and Ge transmit into the far infrared beyond a wavelength of 50 µm.

Due to their inherent lattice structure, crystals exhibit birefringence, polarization behavior, electro-optical properties, and nonlinear optical properties which are exploited in crystal polarizers, modulators, beam-deflection systems, and frequency converters. Birefringent crystals include sapphire, quartz, ammonium dihydrogen phosphate, potassium dideuterium phosphate, and calcite.

Drawbacks of optical crystals in comparison with optical glass include higher price, the solubility of many halide crystals in water (only fluorspar, with a minimum water solubility of 1.5×10^{-3} g/100 cm^3, is moisture-resistant enough for practical purposes), and their cleavage anisotropy, which makes fabrication difficult. Optical anisotropy limits the use of birefringent crystals in imaging optics.

Virtually all optical crystals are grown as single crystals either from solution or from a melt. Exceptions are the natural minerals calcite (for polarizers) and mica (for phase plates).

7. Optical Plastics

When compared with glasses and crystals, organic polymers have the crucial advantage that they can be shaped by injection molding [13] or casting [14], techniques that do not involve the removal of material. As a result, complicated optical components such as Fresnel lenses, aspheric lenses, lens – prism combinations, and lenses with integrally molded mounting parts (Fig. 13) can be manufactured by simple economical methods. Because of their poor quality, however, such components are mainly used in

Figure 12. Transmission curves of optical filter glasses
A) Ion-colored heat filter with gradual absorption edges; B) Dark red tempered glass filter with steep edge; C) Ultraviolet filter with narrow passband; D) Light neutral glass filter

consumer goods. The use of plastic optics represents a cost saving of 5 – 15 % in comparison with glass optics [13].

Figure 13. Plastic lens with integrally cast mounting part

Other advantages of optical plastics over glass are a more than 50 % lower density and a 10-fold lower shock sensitivity and resistance to breakage. Their surfaces are resistant to solvents and can easily be dyed. They can be subjected to seamless welding (polymerization). Refractive index and dispersion can be adjusted by the use of copolymers [15]. Replication techniques can be employed to bond aspheric plastic skins on spherical glass lenses (Fig. 14) [16]. Polarizing or colored films can be polymerized onto the base material.

Figure 14. Replication method for making an aspheric precision plastic lens from a spherical glass lens

a) Lens; b) Mold; c) Release agent; d) Protective coating; e) Monomer; f) Replica layer

The principal disadvantage of optical plastics as compared against glasses is that their op-

tical and mechanical properties are much more (ca. 10-fold) dependent on temperature. This, together with their up to ninefold lower thermal conductivity and up to threefold higher specific heat, leads to different cooling rates at the surface and in interior regions, causing deformations, inhomogeneities in refractive index, and index shifts of up to $\pm 10^{-3}$ [13].

Another important disadvantage of optical plastics is the strong dependence of the optical and mechanical properties on atmospheric humidity. Swelling after water absorption of 0.1 – 0.8 % can lead to dimensional changes as great as 4 %. Absorbed water, even at low concentrations, also alters the refractive index.

Plastics are also less transpartent than optical glass, internal transmittance of a 2 mm thick flat is 0.6 – 1.9 % lower. Plastics have a poorer thermal stability.

Mold shrinkage amounts to 0.4 – 0.7 % for thermoplastics and 4 – 14 % for thermosets, and causes deformation and residual stress in components with large thickness differences.

Other problems include haze due to surface roughness and Tyndall scattering; contamination as a result of the high surface resistivity and buildup of electric charge; aging with yellowing, haze, cold creep, stress corrosion cracking, and shrinkage; poor resistance to scratching and wiping; and poor adhesion of antireflection and reflective coatings.

More than 100 optically practicable polymers are now known, having refractive indices between 1.35 and 1.72 and Abbe numbers between 86 and 18.8 (Fig. 1) [17]. Most are, however, noncommercial laboratory products that are made from expensive monomers or are difficult to process or color. High indices are achieved by adding S, Cl, I, As, or metal ions. Aromatic carbon is especially effective in raising the refractive index, but often yields expensive colored products that are hard to process. An increase in the index, and mostly without intrinsic color, is obtained by bromination or chlorination. Fluoridation or perfluoridation, on the other hand, lowers the index. The most commonly used commercial optical plastic is the crown-glass analogue poly(methyl methacrylate) (PMMA) [18], but this material absorbs a lot of water (0.8 – 4 %) and swells with dimensional changes [19]. It is likely to be replaced by cyclohexylmethyl methacrylate, which is not yet on the market. Another plastic, polymethylpentene (TPX), is a close optical analogue of PMMA; it is lighter than water and has a relatively high thermal stability (180 °C), but shrinks more than PMMA and has twice as high a coefficient of thermal expansion. Teflon, with an extremely low refractive index, can be used only in very thin sections because of its strong scattering.

Polystyrene, a flint-glass analogue, is inferior to PMMA as far as service qualities are concerned. It is increasingly being displaced by the optically analogous but mechanically and thermally superior polycarbonate (bisphenol A – phosgene polycarbonate) [20]. A still higher refractive index of 1.612 is obtained with DPSC (a copolymer of bisphenol and dihydroxyphenyl sulfide).

The gap between PMMA and polystyrene in the $n-\nu$ diagram (Fig. 1) is being filled by styrene copolymers, which, however, often have a slight yellow cast. These include styrene–acrylonitrile (SAN), styrene–maleic anhydride (SMA), polytrifluoromethylstyrene (FMS), and cyclohexylmethyl methacrylate–styrene (CMMAS) copolymers [18]. They have properties markedly better than those of polystyrene. Despite its high dispersion ($\nu \approx 34$), FMS has an extremely low refractive index (1.508).

8. Manufacturing Techniques

8.1. Processing of Optical Glasses

The classical method of producing optical components from optical glasses [21] involves sawing, cutting, nibbling (shanking), and rounding slabs of glass so that as little material as possible has to be removed in the subsequent grinding process. The preparation of optical crystals is similar.

The more economical technique involving molded blanks, which require little grinding, can only be employed with moldable glasses that do not tend (like many high-index dense lanthanum crowns) to recrystallize when under pressure [5]. On economic grounds, blanks of mass-produced glasses are conventiently gobbed from a continuous melter and then molded. There is a trend toward the use of precision-molded lens blanks that are ready for polishing. Condensing lenses

are made in smooth-surfaced molds so that no polishing is needed.

The classical grinding process, involving the use of a loose abrasive and a grinding tool, is being supplanted by grinding (milling) with diamond-ring tools. Multispindle grinding machines with a central drive are being replaced by numerically controlled single-spindle machines [22], [23]. To obtain short polishing times, fine-milled (fine-ground) lens surfaces should have maximum roughnesses of the order of 1 μm.

Grinding is a purely mechanical process. The subsequent polishing step, however, involves chemical reactions between the polishing medium [Fe_2O_3 (rouge) or cerium oxide], the polishing pitch or felt, and the water in which the polishing medium is slurried [24].

Figure 15. Deformation (departure from sphericity) of a spherical surface (A) before and (B) after computer-controlled correction polishing
Diameter = 29 cm; Radius of curvature = −45 cm; λ = 633 nm; Surface deformation: root mean square value 0.012 λ before and 0.004 λ after correction, peak to valley value 0.075 λ before and 0.028 λ after correction

In classical low-precision polishing (e.g., for condenser and spectacle lenses), the tools are equipped with felt, which allows faster polishing; in precision optics, pitch is used. For high-performance optics, composite aids (polishing films and pellets) and synthetic polishing-medium supports are employed to give a surface accuracy of ca. ± 50 nm. In precision optics, however, the lens surfaces may only have a maximum deformation of ± 20 nm or, under some circumstances, ± 10 nm. High precision can be achieved in large-diameter lenses through local computer-controlled correction polishing [26]. Control is based on the use of interferometry to detect deformations in the polished surface to be corrected. The polishing tool is small in comparison with the diameter of the surface being treated, and remains in the relevant surface regions until the surface deformations have been corrected. Figure 15 shows the smoothing of deformations in a spherical surface in such a correction process. Correction polishing can also be done by ion-beam methods [25], the density of the ion beam being modified with perforated masks or aperture control. The ion-beam density corresponds to the thickness of material to be removed.

After polishing, the lenses are centered and edged so that they are bounded by a cylinder whose axis coincides with the optical axis. The optical axis must be aligned with the rotation axis of a spindle accommodating the lens. Alignment can be carried out optically, with the reflected images of luminous points formed at the centers of curvature of the lens surfaces, or mechanically, with a pair of annular cutting edges arranged in tong fashion. The edge of the lens is then milled to a cylindrical form.

Aspheric lenses made from glass by fine milling and polishing have a maximum accuracy of ca. 0.1 μm. With computer-controlled correction polishing or ion-beam etching, spherical surfaces can be deformed in the range of a few tens of nanometers to give nanometer aspherics (Fig. 16) [26].

Figure 16. Deformation (departure from sphericity) profile of a nanometer aspheric made by ion-beam etching with perforated mask control
Diameter = 70 mm; Radius of curvature = 225 mm; λ = 633 nm; Surface deformation: root mean square value 0.068 λ

8.2. Casting of Optical Thermosets

Optical components made of thermosets (e.g., CR 39, epoxy resins) can be fabricated by casting and setting [14]. Thermosets harden by polymerization of a liquid monomer (e.g., diethylene glycol bisallyl carbonate) in a mold. The process is relatively slow and is accompanied

by 4 – 14 % shrinkage. Shrinkage can, however, be reduced by the addition of set resin from the same batch, the use of prepolymerized gels which have already undergone most of their shrinking, or by casting around prefabricated component cores. The rather long setting time can be greatly shortened and the shrinkage minimized by accelerating polymerization with UV light or X-rays.

Diffraction-limited aspheric elements can be produced by polymerizing thin aspheric thermoset layers onto spherical glass lenses (Fig. 14) [27]. This method, called replication, employs aspheric quartz glass molds coated with a release agent (silicone oil). The resin layer is pressed against the substrate by the mold (Fig. 14 B) and sets in under 1 min on exposure to UV irradiation (Fig. 14 C). Because thinner layers shrink less on polymerization, the resin must be no thicker than 0.01 mm to a maximum of 1 mm.

8.3. Processing of Thermoplastic Optical Components

The most rational and economical technology for making plastic optical elements is injection molding of granulated thermoplasts. One die can feed resin to several molds simultaneously so that a number of lenses can be produced in a short cycle time. This technique has the advantage that mounting parts can be molded integrally with the optics. The maximum lens diameter is, however, limited to 30 mm.

Because the properties of injection-molded plastics cannot be adequately controlled, they cannot be employed in high-quality optics. Longer cooling times (ca. 1.6 min) are needed for the injection molding of plastic lenses which may alter material properties. Orientation of the molecular chains in the die during injection into the mold can also result in birefringence [11]. By optimal die temperature control, the shrinkage can be kept to 0.3 – 0.6 % (depending on material and process conditions). This shrinkage can be offset by correction of the mold.

Because of cooling variations, solidification occurs unevenly within the plastic lens. The hardening plastic may also stick to the cooler mold. These problems can be overcome by using ceramic molds, which are poor heat conductors that insulate the entire lens volume and hold it above the solidification temperature for some time. In contrast to steel molds, solidification in ceramic molds is virtually stress-free. However, even with ceramic molds, lenses with large diameters and large edge-to-center differences in thickness cool unevenly resulting in differential shrinkage, deformations, stress birefringence, and inhomogeneities.

1. Introduction

Dental caries (formation of cavities) and periodontal diseases, the two most prevalent human diseases, are both caused by bacteria present in deposits on the teeth. These deposits, also known as plaque, contain a host of microorganisms. Acid-forming microorganisms are responsible for cavities, whereas anaerobes are primarily responsible for the development of gingivitis, are the first step of periodontal diseases. Therefore, bacterial plaque constitutes the basis for the destruction of teeth and their supporting structures [1–3]. Caries and periodontal diseases are estimated to cost insurance companies in the Federal Republic of Germany as much as €8.6×10^9 (ca. \$ 10^{10}) annually, and the cost is rising. Thus oral hygiene has a considerable economic impact on society, quite apart from its obvious advantages to the individual.

Removal of plaque is the key to preventing caries and gum diseases, but effective plaque removal requires a conscientious, daily effort. Most of the actual work is performed by a toothbrush, which constitutes the most important prophylactic agent. The action of the toothbrush is supported by toothpaste that contains cleansing agents to facilitate the removal of firmly bound deposits. Plaque removal from the relatively inaccessible spaces between the teeth requires the use of dental floss. Special interdental brushes serve a similar purpose, but they can be used only when the gaps between the teeth have already been widened by gum resorption. Plaque dyeing tablets make plaque deposits visible, so that the efficiency of their removal can be checked easily. Electric toothbrushes have also been found to be useful in plaque removal, even exceeding the effectiveness of ordinary toothbrushes when properly used [4,5]. Oral irrigators, on the other hand, are not intended for plaque removal, although they can help to eliminate previously dislodged plaque and food residues from inaccessible interdental openings.

All the tools so far described are based on a mechanical plaque-removal strategy. Chemical plaque control is currently possible only with chlorhexidine digluconate [*18472-51-0*], an antimicrobial agent that suppresses plaque deposition because of its high affinity for teeth and the oral mucous membranes [6]. Continuous use of the substance is recommended only in special cases (e.g., in patients with jaw fractures [7]) because long-term application leads to discoloration of dental surfaces. Although discoloration is reversible, it still represents a cosmetic problem.

2. Dentifrices

The agents used to assist a toothbrush in removing plaque are known as dentifrices, they include toothpaste and toothpowder. *Toothpastes* are regarded as cosmetics rather than drugs and are thus subject only to legal restrictions applicable to cosmetics, including regulations governing the amount and type of dyes, preservatives, and fluorine compounds they may contain. Most commercially distributed toothpaste falls into one of four major categories: *medicinal, anticaries, antitartar,* and special *pediatric* toothpaste. The precise formulation of a toothpaste is a function of the purpose for which it is intended. Medicinal toothpaste contains ingredients designed to combat inflammation of

© 2005 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim
10.1002/14356007.a18_209

the gums, whereas fluoride is the most important additive in toothpaste aimed at prevention of caries. Many toothpastes offer significant protection against the formation of tartar, but they cannot remove existing tartar deposits [8]. Because children perceive tastes differently from adults, special pediatric toothpastes have been developed [9]. These usually have fruit flavors and a low fluoride level. The latter is dictated by a concern for possible fluorosis reactions, particularly in children receiving supplemental doses of fluoride in tablet form. In clear gels hydrated silica is used as the cleansing agent; all other abrasive agents produce opaque (white) toothpastes. *Tooth powder* plays a much more limited role in oral hygiene than toothpaste, perhaps because its application by toothbrush is less convenient. Furthermore, toothpaste produces the sensation of being more evenly distributed throughout the mouth. Nevertheless, tooth powder can include active ingredients that are unstable in a medium containing water.

2.1. Toothpaste

2.1.1. Composition

Toothpaste contains active ingredients and auxiliaries. The active ingredients include:

1) cleansing agents,
2) fluorine compounds,
3) surfactants, and
4) other ingredients.

Auxiliaries include:

1) moisturizers,
2) binders,
3) preservatives,
4) flavoring agents,
5) sweeteners, and
6) dyes.

Cleansing Agents. Cleansing agents are usually insoluble, inorganic substances that constitute 15 – 60 wt % of a typical toothpaste. These materials, which might also be described as polishing agents or abrasives, enhance the cleansing action of the toothbrush and reduce the time required for cleaning. Their effectiveness depends on removing plaque deposits with a minimum of abrasion. The particle size of cleansing agents must be such that individual grains are not perceived as foreign bodies in the mouth; the preferred mean particle size is < 15 µm. The cleansing effect of such particles depends on their size, shape, and hardness.

The most commonly employed cleansing agents are aluminum hydroxide [$Al(OH)_3$], calcium carbonate ($CaCO_3$), calcium hydrogen phosphate dihydrate ($CaHPO_4 \cdot 2H_2O$), calcium hydrogen phosphate ($CaHPO_4$), hydrated silica ($SiO_2 \cdot H_2O$), sodium aluminum silicate [e.g., with the zeolite structure $Na_{12}(AlO_2)_{12}(SiO_2)_{12} \cdot 27\ H_2O$], insoluble sodium metaphosphate [$(NaPO_3)_n$], and hydroxyapatite [$Ca_5(PO_4)_3OH$].

Some toothpastes also contain the soluble cleansing agent sodium hydrogen carbonate, usually mixed with calcium carbonate. The soft sodium hydrogen carbonate often consists of relatively large particles and is referred to as a "temporary cleansing agent" because it slowly dissolves in saliva during brushing. A very finely divided form of the water-insoluble, organic cleansing agent poly(methyl methacrylate) is also sometimes employed.

Fluoride in toothpastes increases the resistance of dental enamel against attack by the acid released by bacterial plaque; it also facilitates remineralization of the enamel. Fluoride is thus essential in toothpaste for caries prophylaxis. The most commonly employed fluorine compounds are sodium fluoride, sodium monofluorophosphate, and certain organic amine fluorides [e.g., bis-(hydroxyethyl)-aminopropyl-*N*-hydroxyethyloctadecylamine dihydrofluoride].

Surfactants (foaming agents) lower surface tension and contribute to the uniform distribution of toothpaste during brushing. They also increase cleansing power, especially at sites that are difficult or impossible to reach with a toothbrush. Obviously, the only surfactants that can be considered for toothpaste are those that are physiologically safe, they should also have as neutral a taste as possible. The most commonly used surfactants include sodium lauryl sulfate, sodium lauryl sarcosinate, sodium cocoate, sodium lauryl sulfoacetate, sodium cocomonoglyceride sulfonate, and betaines.

Other Active Ingredients. This category includes substances that either strengthen enamel (e.g., remineralizers) or have an effect on plaque (e.g., antimicrobial agents, plaque suppressants, tartar control agents, or enzymes). Additional possibilities include components with a beneficial effect on the oral mucous membranes, such as anti-inflammatory agents, astringents, or vasoactive agents.

Moisture control agents primarily minimize the tendency of a toothpaste to dry out but also affect its consistency and enhance its stability in the cold. The most common moisture control agents for toothpaste are glycerol, sorbitol, xylitol, 1,2-propylene glycol, and poly(ethylene glycol).

Binders and thickeners determine the consistency of toothpaste and prevent the separation of liquids and solids. The principal binders are natural and synthetic hydrophilic colloids such as alginates, carrageenan, tragacanth, sodium carboxymethyl cellulose, hydroxyethyl cellulose, methyl cellulose, methyl hydroxypropyl cellulose, xanthan gum, and guar gum. Typical thickeners are highly dispersed silica, magnesium aluminum silicate, magnesium lithium silicate, and bentonite.

Sweeteners improve the taste of a toothpaste. The use of sodium saccharine is especially widespread, often in combination with sodium cyclamate. Acesulfame-K and aspartame have also been utilized.

Preservatives are required to protect toothpaste from microbial decomposition. The most important preservatives for this purpose are esters of 4-hydroxybenzoic acid, or benzoic acid and its sodium salt, as well as sorbic acid and potassium sorbate. Compounds such as 2-hydroxybiphenyl, bromochlorophene, dehydroacetic acid, and chlorhexidine have also been employed.

Dyes. Both water-soluble and water-insoluble dyes are used in toothpaste. Water-insoluble lakes and pigments are particularly common for dyeing multicolored, "striped" products, where migration of color into the white toothpaste base must be prevented. The most frequently used dyes are cochineal red A (C.I. 16 255), patent blue V (C.I. 42 051), indigotine (C.I. 73 015), chlorophyll (C.I. 75 810), quinoline yellow (C.I. 47 005), titanium dioxide (C.I. 77 891), indanthrene blue RS (C.I. 69 800), and madder lake (C.I. 58 000). All of these dyes have high resistance to acid and base, as well as excellent temperature stability.

Flavoring Agents. A wide range of flavoring agents can be found in toothpaste, in most cases introduced as mixtures. The essential oils listed in Table 1 are described in more detail elsewhere (→ Flavors and Fragrances).

Table 1. Flavoring agents used in toothpaste

Substance	Origin
American peppermint oil	*Mentha piperita*
Brazilian peppermint oil	*Mentha arvensis*
Spearmint oil	*Mentha crispa*
Anise oil	*Pimpinella anisum*
Eucalyptus oil	*Eucalyptus globulus*
Fennel oil	*Foeniculum vulgare*
Lemon oil	*Citrus limon*
Wintergreen oil	*Gaultheria procumbeus*
Clove oil	*Eugenia caryophyllata*

Flavor specialists have devoted considerable attention to improving the taste of toothpaste with additives. The aim is to increase overall acceptance of the product and thus raise the conscientiousness of the public with respect to hygiene. Cleansing agents such as calcium carbonate, calcium phosphate, hydrated silica, aluminum hydroxide, and sodium metaphosphate can bind fairly large amounts of flavoring components.

Peppermint-flavored toothpastes represent 35 % of the world market. They are distributed throughout the world and are particularly common in Europe (especially Scandinavia, UK, and FRG), playing a smaller role in the United States and Asia. The generic formulation (in weight percent) is

Peppermint oil	ca. 60
Menthol ex peppermint oil	10 – 15
Anise oil, fennel oil	10 – 15
Eucalyptus oil	5 – 10
Spice oils	2 – 5
Nuance substances (floral oils, lemon oil)	0.5 – 10

Spearmint-flavored products represent 40 % of the market. These are also found worldwide, especially in the United States and Asia (less

in Europe). The generic formulation (in weight percent) is

Spearmint oil	ca. 30 – 40
Peppermint oil	20 – 30
Menthol ex peppermint oil	10 – 15
Anise oil, fennel oil	10 – 15
Spice oils	0.5 – 3
Nuance substances	0.1 – 5

Wintergreen-flavored toothpastes account for 20 % of the world market, primarily in the United States and the Philippines. The generic formulation (in weight percent) is

Peppermint oil	ca. 20 – 30
Spearmint oil	5 – 20
Menthol ex peppermint oil	5 – 10
Anise oil, fennel oil	10 – 30
Eucalyptus oil	10 – 20
Wintergreen oil	10 – 30
Spice oils	1 – 10
Nuance substances	1 – 2

Peppermint-anise toothpastes are particularly common around the Mediterranean, accounting for 5 % of the world market. The generic formulation (in weight percent) is

Peppermint oil	ca. 10 – 30
Spearmint oil	10 – 15
Menthol ex peppermint oil	5 – 10
Anise oil, fennel oil	30 – 40
Eucalyptus oil	5 – 20
Spice oils	1 – 2
Nuance substances	2 – 3

Examples of complete toothpaste formulations follow (values are in weight percent):

Toothpaste for gingival prophylaxis	
Methyl cellulose	1.10
Sorbitol, 70 %	15.00
Water	31.00
Sodium saccharin	0.05
Carbamide	5.00
Sodium benzoate	0.20
α-Bisabolol	0.10
Sage extract	0.50
Flavoring agent	1.10
Methyl 4-hydroxybenzoate	0.15
Calcium carbonate	45.00
Sodium cocoate	0.80
Anticaries toothpaste	
Sodium carboxymethyl cellulose	1.40
Sorbitol, 70 %	28.00
Xylitol	5.00
Water, deionized	43.37
Acesulfame-K	0.25
Sodium fluoride	0.24
Methyl 4-hydroxybenzoate	0.18
Propyl 4-hydroxybenzoate	0.06
Flavoring agent	1.00
Silicic acid abrasive	11.00
Silicic acid thickener	8.00
Sodium lauryl sulfate	1.00
Fatty acid tauride	0.50
Antitartar toothpaste	
Sorbitol, 70 %	15.00
Carrageenan	0.80
Glycerol	27.00
Poly(ethylene glycol), PEG-12	2.00
Sodium lauryl sulfate	1.40
Silicic acid abrasive	20.00
Tetrapotassium pyrophosphate	4.50
Tetrasodium pyrophosphate	1.50
Titanium dioxide	0.50
Sodium saccharin	0.25
Flavoring agent	1.00
Sodium fluoride	0.24
Methyl 4-hydroxybenzoate	0.10
Water	25.71
Toothpaste for sensitive teeth	
Hydroxyethyl cellulose	1.40
Glycerol	18.00
Sorbitol, 70 %	12.00
Water	38.68
Sodium saccharin	0.35
Dye (C.I. 45 430)	0.01
Methyl 4-hydroxybenzoate	0.10
Propyl 4-hydroxybenzoate	0.06
Strontium chloride hexahydrate	10.50
Flavoring agent	1.00
Hydrated silica	15.00
Silica, highly dispersed	1.60
Sodium lauryl sulfate	1.30

2.1.2. Production

Toothpaste can be prepared in a batchwise or continuous process at any desired temperature. Cold processing (ca. 25 °C) is generally employed.

Process. The charge anticaries formulation is generally prepared in a 200 – 2500-L vacuum mixer equipped with a planetary stirrer and homogenizers. Sorbitol is introduced first, in which sodium carboxymethyl cellulose is then suspended with stirring. Deionized water is added with continued stirring followed by acesulfame-K, sodium fluoride, xylitol, and the two hydroxy benzoate esters. Stirring is maintained for ca. 20 min until the binder has finished swelling and all water-soluble components are dissolved. The mixer is then evacuated. As soon as the vacuum has reached 2 – 3 kPa, silicic acid abrasive, fatty

acid tauride, and sodium lauryl sulfate are drawn in and the mass is intensively stirred and homogenized for ca. 15 min. The flavoring agents are drawn in last, stirring and homogenization are maintained at full intensity under vacuum for ca. 10 min. until all bubbles have been removed to produce the desired smoothness and the mixture shows a homogeneous structure.

Continuous Process. Most continuous processes for toothpaste manufacture involve six production steps: gel preparation, introduction of liquid components, addition of solids, mixing, homogenization, and degassing.

Gel Preparation. The gel in a typical commercial toothpaste consists mainly of a mixture of glycerol, sorbitol, and binding agent. Problems are most likely to arise during the blending step because the formation of lumps is difficult to avoid with binding agents such as sodium carboxymethyl cellulose. The powder – liquid mixture is passed through a three-stage colloid mill equipped with a specially designed intake screw. Entrapment of finely divided air cannot be avoided and because this could lead to subsequent problems, the output of the colloid mill is passed through a dynamic degasser capable of continuously degassing the gel at its standard input density.

Introduction of Liquid Components. Liquid components are added through volumetric metering pumps. A separate metering head is best used for each liquid component, although premixing is also employed.

Mixing. The biggest problem in continuous processing involves the metering of solid components. The required quantity of mixture must be worked uniformly into the liquid stream. A homogeneous powder mixture is therefore needed. The densities of the individual raw materials can vary from 0.2 to 1.3 g/mL, their contents ranging from 0.5 – 95 % of the amount of powder. Metering may be accompanied by relatively rapid demixing because the powders in the metering vessel flow at different rates depending upon their densities. Screw metering is therefore preferred because it provides good metering accuracy over a variable performance range. Reproducible bulk density is achieved with the aid of preliminary loosening and homogenization of the charge.

The powder and liquid phases are mixed in a conical mixer containing an anchor screw device and a dissolver to ensure prehomogenization of the product. The process is conducted at atmospheric pressure, and entrapped air is subsequently removed with a dynamic degasser.

Homogenization is achieved with a rotary piston pump controlled by a level regulator installed on the mixer. The rotary piston pump transports the toothpaste into a three-stage inline colloid mill.

Degassing is performed in a dynamic degasser. The residence time and thus degassing is controlled with an exit pump subject to microwave adjustment.

2.1.3. Quality Specifications, Analysis, and Testing

Toothpaste is usually stable for at least 30 months even under variable temperature conditions. Physical, chemical, or biological changes can affect its quality. Oral hygiene products are therefore tested during product development for their storage behavior after 1 – 3 months at + 40, + 5, and – 10 °C, as well as after at least 6 months at 20 °C. Results are normally judged on the basis of consistency, color, taste, pH, fluoride content, content of other active ingredients, tube corrosion, gas generation, liquid separation, and microbiological stability [10, 11].

As noted earlier, oral hygiene products may contain many diverse ingredients. The variety of products and starting materials, as well as the multitude of potential test methods in a modern analytical laboratory, makes it difficult to provide a brief, product-oriented summary of oral hygiene product analysis. For detailed information see [12].

Toothpastes are subjected to both in vitro and in vivo testing with respect to their effectiveness. In vitro tests consist mainly of microbiological investigations and studies dealing with remineralization, whereas in vivo tests are designed to check product effectiveness in preventing caries and gingivitis [13–17].

2.2. Tooth Powder

Tooth powder differs from toothpaste primarily because of the absence of moistening agents such as glycerol, sorbitol, and water. As a result, the cleansing agent content can be as high as 90 %. The following formulation (in weight percent) is typical of a tooth powder designed for gingival prophylaxis:

Sodium carboxymethyl cellulose	1.50
Poly(ethylene glycol) 1500	4.00
Sodium saccharin	0.30
Aluminum lactate	8.00
Flavoring agent	1.40
Calcium carbonate	73.90
Sodium hexametaphosphate	6.00
Silicon dioxide, highly disperse	3.50
Sodium lauryl sulfate	1.40

3. Mouthwashes

Mouthwashes are generally not suitable for removing plaque and therefore can not replace toothbrushes and toothpaste. They mainly serve to give the user a certain feeling of freshness and to mask bad breath. To achieve this, mouthwashes contain alcohol and high concentrations of essential oils. Mouthwashes are sold as ready-to-use solutions or as concentrates to be diluted with water. A relatively simple percentage composition for a refreshing mouthwash is given in the following example::

Ethanol (94.7 %)	80.00
Sodium cyclamate	0.15
Flavoring	3.50
Red dye (C.I. 16 255)	0.01
Water, demineralized	16.34

Apart from mouthwashes designed to give a purely refreshing effect, there are also mouthwashes that provide a certain degree of prophylaxis against caries and periodontitis. These mouthwashes, available exclusively as ready-to-use solutions, contain active ingredients such as sodium fluoride or antibacterial substances like cetylpyridinium chloride. However, these mouthwashes alone do not provide adequate oral prophylaxis, and they should be used in combination with the usual oral hygiene measures, either to intensify the remineralizing and enamel-strengthening action of sodium fluoride or to provide antibacterial activity against residual plaque. A typical example of the percentage composition of a sodium fluoride-containing mouthwash is:

Ethanol (94.7 %)	7.000
Glycerol (86 %)	12.000
Sodium fluoride	0.050
Pluronic F-127 (emulsifier)	1.400
Sodium phosphate (buffer, pH 7)	1.100
Sorbic acid	0.200
Sodium saccharide	0.150
Red dye (C.I. 15 850)	0.002
Water, demineralized	77.998

4. Denture Cleansers

Removable dentures must also receive daily cleansing because they are just as subject to plaque deposition as natural teeth, and the associated bacteria cause infections of the oral mucous membranes. Special tablets and powders with antibacterial properties have been developed to facilitate mechanical plaque removal from dentures; these function much like detergents. All raw materials used in denture cleansers must meet regulatory standards for cosmetic agents.

Most denture cleansers contain 1 – 4 % active oxygen as their bactericidal component, which is released in aqueous solution as peroxo compounds. The effervescence that accompanies oxygen release supports the chemical cleansing action of the accompanying surfactants and helps in the mechanical removal of adhering particles. Generic formulations for denture cleansers are given in Table 2.

Table 2. Formulations of dental cleansers

Component	Content, wt %	
	Powder	Tablet
Sodium peroxoborate	20 – 25	20 – 25
Potassium peroxosulfate		20 – 30
Sodium tripolyphosphate	20 – 25	10 – 25
Sodium hydrogen carbonate	20 – 25	10 – 15
Citric acid		15 – 20
Sodium dodecylbenzenesulfonate	0.5 – 1	0.3 – 1
Sodium sulfate	25 – 30	20 – 25
Indigotine	0.005 – 0.02	0.005 – 0.02
Flavoring agent	0.5 – 1	0.5 – 1
Tableting agents		5

1. Introduction [1–12]

Organometallic compounds are substances in which a metal or metalloid is involved in at least one direct bond to a carbon atom, whereby the bond can have either covalent or ionic character. Table 1 shows a section of the periodic table, listing those elements whose organic derivatives are regarded as organometallic compounds.

Table 1. Range of organometallic compounds in the periodic table

1	2	3	4	5	6	7	8	9	10	11	12	13	14	15	16
Li	Be											B			
Na	Mg											Al	Si	P	
K	Ca	Sc	Ti	V	Cr	Mn	Fe	Co	Ni	Cu	Zn	Ga	Ge	As	Se
Rb	Sr	Y	Zr	Nb	Mo	Tc	Ru	Rh	Pd	Ag	Cd	In	Sn	Sb	Te
Cs	Ba	La$^+$	Hf	Ta	W	Re	Os	Ir	Pt	Au	Hg	Tl	Pb	Bi	(Po)
Fr	Ra	Ac∗													

La$^+$ = Lanthanum and lanthanides; Ac∗ = Actinium and actinides.

In this article, only some important examples of organometallic compounds are described: the organic derivatives of lithium, magnesium, zinc, mercury, and boron are important reagents in organic synthesis, while organometallic compounds of aluminum, silicon, tin, and lead are produced industrially on a large scale. With few exceptions (e.g., iron pentacarbonyl), organotransition metal complexes have found only limited application in industrial stoichiometric reactions. On the other hand, they act as intermediates in transition-metal catalysis, in which they largely control the course of the reaction.

Although the first organometallic compound, $[(CH_3)_2As]_2O$ [*503-80-0*], was prepared as early as 1760, it was only in the late 1800s that the first major developments began, with the seminal work of LUDWIG MOND on the carbonyls of nickel and iron and the discovery of the Grignard reagents. The systematic study of organo transition metal complexes and their potential in catalysis began in the mid-1900s with the work of W. REPPE, E. O. FISCHER, K. ZIEGLER, and G. WILKINSON. Some important discoveries of organometallic compounds are listed in Table 2.

Table 2. Historical development of organometallic chemistry

Year	Discoverer	Compound

1981	R. West	$R_2Si{=}SiR_2$

Closely linked to the development of synthetic organometallic chemistry is the development of heterogeneous and homogeneous catalysis. Some noteworthy discoveries in this field are listed in Table 3.

2. Organometallic Compounds of the Main Group Elements [13–34]

2.1. Group 1

Organolithium compounds (→ Lithium and Lithium Compounds, Chap. 6.2.) are usually prepared from lithium metal or from commercially available *n*-butyllithium. In the first case, lithium metal is treated with an organic halide to give an organolithium compound and a lithium halide. In the second case, a metallation reaction, *n*-butyllithium is treated with an organic compound containing an acidic C – H group, forming an organolithium compound with liberation of butane. In their chemical behavior, the organolithium compounds resemble the Grignard reagents; they are, however, more reactive. Organolithium compounds have gained importance industrially as initiators for the polymerization of isoprene, in which a polyisoprene that is closely related to natural rubber is formed.

The organic derivatives of the heavier alkali metals are of only minor importance. The ionic character of the metal – carbon bond increases from lithium to cesium. Methylsodium [*18356-02-0*] and methylpotassium [*17814-73-2*] are so reactive that they can even metallate alkanes.

2.2. Group 2

Because of their high air and moisture sensitivity and extreme toxicity, the organoberyllium compounds play only a minor role in synthetic chemistry. In contrast, the organomagnesium halides, or Grignard reagents, are of major importance (see also → Magnesium Compounds, Chap. 6.). They are synthesized from iodine-activated magnesium turnings and an or-

ganic halide RX. In ethereal solution the Grignard reagents exist in the Schlenk equilibrium:

The reactivity of the Grignard reagents is demonstrated by their behavior towards compounds having active protons. For example, the action of water leads to liberation of an alkane; the same is true for reactions with alcohols, carboxylic acids, and amines. In the case of methylmagnesium iodide [*917-64-6*], this reaction can be used to determine the number of active protons in an organic compound by measuring the amount of methane released gas volumetrically (Zerewitinow reaction).

The same reaction is used for selective deuterium labelling of alkanes with D_2O; for example:

Also of importance is the reaction of Grignard reagents with compounds that contain polar multiple bonds, such as C=O, C=N, C≡N, or C=S. Thus, reaction with carbon dioxide followed by hydrolysis affords carboxylic acids, long-chain aldehydes give secondary alcohols, formaldehyde affords primary alcohols, and ketones afford tertiary alcohols. Some important reactions of Grignard reagents, together with their hydrolysis products, are as follows:

Apart from the Grignard reagents, numerous other organomagnesium compounds are known. Examples are magnesium butadiene [*70809-00-6*] and magnesium anthracene [*50594-04-2*], which are formed by reaction of magnesium with C=C double bond systems.

2.3. Group 12

The first organozinc compounds were prepared by E. Frankland in 1849. For example, diethylzinc [*557-20-0*] is formed by reaction of zinc with ethyl iodide, after distillation of the initially formed ethylzinc iodide [*999-75-7*]:

Organozinc compounds are also of importance in the Reformatsky reaction, in which α-halo carboxylic acid esters are converted to organozinc derivatives, which then add to the C=O double bond of aldehydes or ketones. The organozinc intermediate exists as a dimer:

A further synthetic application of organozinc compounds is the cyclopropanation of alkanes (Simmons – Smith reaction). The key starting material for this reaction is (iodomethyl)zinc iodide [*4109-94-8*], which can be obtained by reaction of zinc with diiodomethane. The Simmons – Smith reaction is stereospecific, so that, for example, *cis*-alkenes give exclusively *cis*-cyclopropane derivatives. The attack of the carbenoid on the double bond does not involve the

free carbene, but instead occurs by a concerted reaction:

Organocadmium compounds are very similar to the organozinc compounds, but somewhat less reactive. Organomercury compounds are unusual in that the inert, covalent mercury–carbon bond is very stable to water and air. For this reason, organomercury compounds were used in the past as pharmaceuticals, fungicides, and bactericides. These uses have, however, declined drastically due to the toxicity of these compounds. Organomercury compounds have some importance in organic synthesis. In mercuration reactions, aromatic, heteroaromatic, or aliphatic compounds which contain acidic hydrogen atoms are reacted with mercury(II) acetate to form organomercury derivatives that can undergo a range of subsequent reactions. The hydroxymercuration of alkenes with mercury(II) acetate in the presence of water leads to regioselective formation of (hydroxyalkyl)-mercury compounds, which can be converted to alcohols by reaction with sodium borohydride in situ. The overall reaction corresponds to markovnikov addition of water across the C=C double bond:

In the Seyferth dihalocyclopropanation reaction, dihalocarbenes are formed from organomercury compounds and then add to unsaturated compounds, for example, cyclohexene:

2.4. Group 13

Organoboron compounds can be synthesized by reaction of boron trifluoride with Grignard reagents or through addition of diborane [*14044-65-6*], B_2H_6, to alkenes, the hydroboration reaction (cf. Section 3.2.8):

Trialkylboranes are very sensitive to oxidation and may undergo self ignition on contact with atmospheric oxygen. Therefore, trialkylboranes are usually reacted further in situ, for example, by protolysis to give alkanes or by oxidation to alcohols with hydrogen peroxide.

Since the hydroboration of unsymmetric alkenes always affords the anti-markovnikov product, the subsequent oxidation with hydrogen peroxide leads to primary alcohols. Overall, the reaction can be regarded as anti-markovnikov addition of water to an alkene:

In addition to high regioselectivity, hydroboration also exhibits high stereoselectivity for *cis* addition. Particularly high selectivity is exhibited by organoboron compounds with sterically demanding substituents, such as 9-borabicyclo[3.3.1]nonane (9-BBN) [*280-64-8*], which is synthesized from diborane and 1,5-cyclooctadiene [*1552-12-1*]. Since hydroboration is a reversible reaction, alkylboron compounds can undergo elimination of alkenes at higher temperatures. This reaction can be used for the formally contra-thermodynamic isomerization of alkenes:

In addition to acyclic boranes, numerous cyclic boranes are also known. Some important examples are the aforementioned 9-BBN, borolane [*1692-31-5*], borole [*287-87-6*], borinane [*289-53-2*], and borobenzene [*31029-61-5*], which generally require stabilization by substitution.

Aluminum alkyls are prepared on an industrial scale. An important method of synthesis is the Ziegler direct synthesis from aluminum, hydrogen, and α-olefins, a cyclic process involving "growth" and "addition" reactions. The two-step process can be summarized as shown here for triethylaluminum [*97-93-8*]:

Growth reaction:

$$Al + 1.5\,H_2 + 2(C_2H_5)_3Al \longrightarrow 3(C_2H_5)_2AlH$$

Addition:

$$3(C_2H_5)_2AlH + 3\,C_2H_4 \longrightarrow 3(C_2H_5)_3Al$$

Overall reaction:

$$Al + 1.5\,H_2 + 3\,C_2H_4 \longrightarrow (C_2H_5)_3Al$$

Aluminum alkyls are also produced industrially by reaction of aluminum or aluminum–magnesium alloys with alkyl halides.

The binary aluminum alkyls are very air and moisture sensitive liquids. The short-chain alkyls undergo self-ignition and react explosively with water. Aluminum alkyls form dimers, which can be considered to contain sp^3 hybridized aluminum and carbon atoms. For example, trimethylaluminum [*75-24-1*] has two bridging methyl groups:

Organoaluminum compounds have various uses in industrial chemistry. An important application is in the Ziegler growth reaction (see figure below). In this reaction, ethene inserts into Al–C bonds, after which either α-olefins are formed in a subsequent displacement reaction (Alfen process, see → Hydrocarbons) or the chain-growth products are first oxidized and then converted to long-chain primary alcohols by hydrolysis (Alfol process, → Fatty Alcohols, Chap. 2.4.1.).

The second important application is the use of aluminum alkyls in Ziegler–Natta catalysis (cf. Section 3.2.4). Ziegler–Natta catalysts are composed of a transition-metal compound (e.g., $TiCl_4$, VCl_3, or Cp_2TiCl_2) and an organoaluminum compound, which may also contain halide substituents (e.g., $AlEt_3$, $AlEt_2Cl$, or $AlEtCl_2$).

Aluminum alkyls are also used for the dimerization of alkenes. For example, in the presence of AlR_3, propene undergoes dimerization to give 2-methyl-1-pentene, which can be converted to isoprene by isomerization and elimination of methane.

The Dimersol process of the Institut Français du Pétrol (IFP) (→ Hydrocarbons) involves the dimerization of propene or the codimerization of propene and butene in the presence of catalysts consisting of aluminum alkyls and nickel compounds. After hydrogenation, the products are effective octane enhancers for motor fuels.

A further important use of aluminum trialkyls is as alkylating agents, for example, in the synthesis of organozinc and organotin compounds. The addition of alkyl aluminum hydrides to double bonds (hydroalumination) is discussed in Section 3.2.8.

Organometallic compounds of gallium and indium are used for doping semiconductors. Coatings of gallium arsenide can be prepared by thermal decomposition of a mixture of trimethylgallium [*1445-79-0*] and arsine.

$$GaMe_3 + AsH_3 \xrightarrow{\Delta} GaAs + 3\,CH_4$$

2.5. Group 14

The organosilicon compounds (→ Silicon Compounds, Organic) are of major industrial importance. They can be obtained by reaction of silicon tetrachloride [*10026-04-7*] with Grignard reagents. The Müller–Rochow synthesis was especially developed for the production of methylchloro-silanes.

The direct Müller–Rochow process always gives a mixture of all possible methylchlorosilanes. These can, however, be separated by distillation. The reaction of the chloromethane takes place on the surface of a copper–silicon alloy, which is prepared from nine parts silicon and one part copper in a sinter furnace.

The methylchlorosilanes are used for the production of silicones (→ Silicones). Hydrolysis of the isomeric mixture of methylchlorosilanes leads to intermediate silanols, which undergo polycondensation to form linear chains and networks of Si–O bonds, whereby the difunctional dimethyldichlorosilane [*75-78-5*] acts as a chain-extender, monofunctional trimethylchlorosilane [*75-77-4*] as a chain-terminator, and trifunctional methyltrichlorosilane [*75-79-6*] as a network-former. The silicones are used as oils, resins, and elastomers.

More recently, organosilicon compounds have been used for the production of ceramics. For example, alkyl- and arylchlorosilanes can be converted by dechlorination to polycarbosilanes, which can be melt-spun into ceramic fibers. The final product is a β silicon carbide with exceptionally high tensile strength.

The organometallic compounds of germanium have no industrial uses as yet. Organotin compounds, in contrast, are readily accessible and have versatile applications. They can be prepared by reaction of $SnCl_4$ with Grignard reagents, with aluminum alkyls, or with alkyl halides in the presence of sodium.

Other important preparation methods are the direct synthesis from tin and alkyl halides and the addition of organotin hydrides to double bonds (hydrostannation). The most important uses of organotin compounds are as stabilizers for PVC, as biocides in industry and agriculture, and as catalysts for the synthesis of polyurethanes. In PVC, organotin compounds suppress the elimination of HCl that occurs during heat treatment. Furthermore, they prevent the photochemical decomposition of the polymer by terminating UV-induced radical chain reactions (→ Plastics, Additives). Organotin compounds such as bis(tributyltin) oxide [*56-35-9*] are used as industrial biocides. Owing to their antibacterial and fungicidal properties, they are used as antifouling agents for wood and for disinfecting circulating cooling water in industrial plants. Triphenyltin acetate [*900-95-8*] and tris(cyclohexyl)tin hydroxide [*13121-70-5*] are used in agriculture as acaricides and for the treatment of algal infestations in rice and potato rot. Important for this application is that the toxicity of the organotin compounds decreases with decreasing extent of alkylation. The organotin compounds undergo degradation in nature as follows:

$$R_4Sn \longrightarrow R_3SnX \longrightarrow R_2SnX_2 \longrightarrow RSnX_3 \longrightarrow SnX_4$$

The final product of this sequence is nontoxic tin dioxide.

Industrially, the most important organolead compound is tetraethyllead [*78-00-2*], which is

produced by reaction of sodium – lead alloy with ethyl chloride under pressure.

$$4\,PbNa + 4\,EtCl \longrightarrow PbEt_4 + 4\,NaCl + 3\,Pb$$

The lead formed in the reaction is reconverted with sodium to the alloy NaPb. An alternative method is the electrochemical Nalco process, in which an ethyl Grignard is converted to tetraethyllead at a lead anode. Tetraethyllead is used as an antiknock for gasoline. Its effectiveness is due to the deactivation of hydroperoxides by lead oxide. However, because of its toxicity its use as an octane enhancer has greatly declined. In the long term, a total ban on lead in gasoline can be expected.

3. Transition Metals

3.1. Transition-Metal Complexes [35–94]

In addition to *s*- and *p*-orbitals, transition metals also possess *d*-orbitals for the formation of metal-carbon bonds. The partial occupation of the *d*-orbitals means that transition metals can act as electron donors and as electron acceptors. A ligand can therefore be bound through both a σ-bond and a π-back-bond. Moreover, transition metals can form direct or ligand-bridged metal – metal bonds, allowing the formation of clusters (see Section 3.1.3). Table 4 gives a survey of transition metal complexes according to ligands.

Table 4. Survey or organometallic transition-metal complexes

Type	Bonding modes (examples)
Alkyls	$M-CR_3$
Aryls	M–
Carbenes	$M=CR_2$
Carbynes	$M\equiv CR$
Carbonyls	$M-C\equiv O$ π-Complexes:	
Alkene complexes	$M-\parallel^{CR_2}_{CR_2}$
Alkyne complexes	$M-\equiv^{CR}_{CR}$ $M\langle^{CR}_{CR}$
Allyl complexes	
Cyclopentadienyl complexes	
Arene complexes	

3.1.1. Alkyls and Aryls

The transition-metal alkyls contain only σ-bonds between the metal and carbon. Only a few of the various methods of synthesis are described here. Transmetallation is the reaction of a metal halide with a main-group metal alkyl, for example, a lithium alkyl or a Grignard reagent. The lithium reagents react more quickly than the Grignards and give the higher alkyls. Metallacycles are accessible by using dilithium alkyls.

Another synthetic method for the preparation of metal alkyls is the insertion of alkenes into metal-hydride bonds (hydrometallation).

$$(CO)_4CoH + CH_2{=}CHR \longrightarrow (CO)_4Co-CH_2CH_2R$$

This reaction plays a role in many important homogeneous catalytic processes. Some transition-metal hydrides can be converted to alkyl complexes by reaction with diazomethane.

$$CpMo(CO)_3H + CH_2N_2 \longrightarrow CpMo(CO)_3CH_3$$

A further important method is the oxidative addition of alkyl halides to 16-electron complexes, a reaction in which the oxidation state of the metal increases by two. Aryl complexes can be obtained by the same method.

$$(PPh_3)_2Ir(CO)Cl + CH_3I \longrightarrow (PPh_3)_2Ir(CO)(CH_3)ICl$$

$$Ni(PPh_3)_4 + PhCl \longrightarrow (PPh_3)_2Ni(Ph)Cl + 2\,PPh_3$$

Many transition-metal alkyls are, however, unstable and can decompose by β-elimination, giving a metal hydride and an alkene (i.e., the reverse of hydrometallation).

Alkyl complexes can be stabilized by using alkyl groups that have no β-hydrogen atoms, for instance, neopentyl or benzyl.

3.1.2. Carbenes and Carbynes

Metal carbene complexes are compounds having metal – carbon double bonds. The first carbene complex was prepared by E. O. FISCHER in 1964 by addition of a lithium alkyl to tungsten hexacarbonyl, giving a complex with a heteroatom substituted alkylidene ligand (Fischer carbene complex).

In 1975, SCHROCK found a route to C – H substituted carbene complexes (Schrock carbene complexes). The synthesis is based on the α-elimination of a hydrogen atom from an alkyl group.

Transition-metal carbene complexes have received much attention because they are intermediates in homogeneous catalytic metathesis reactions (see Section 3.2.5). Carbene complexes are also used in organic synthesis. Thus, Tebbe's reagent can be used to convert a C=O group to C=CH_2, analogously to the Wittig reaction.

The reactive intermediate is $Cp_2Ti{=}CH_2$ [*83876-46-4*].

The first transition-metal carbyne complexes were also synthesized by Fischer.

3.1.3. Carbonyls and Clusters

Carbon monoxide bonds to transition metals through both σ-donor and π-acceptor bonds. Since the metals of groups 3 to 5 have either an insufficient number of d-electrons or none at all, they do not form stable carbonyl complexes. Vanadium hexacarbonyl [*14024-00-1*], for example, decomposes at $-70\,°C$. A survey of the neutral binary carbonyls of groups 5 to 10 is given in Table 5.

As shown in Table 4, carbon monoxide exhibits various bonding modes, acting for example as a terminal ligand and as a doubly or triply bridging ligand. This leads to a wide variety of structures, particularly for the polynuclear clusters. Some examples of the structures are given here for iron and cobalt carbonyls.

Table 5. Neutral metal carbonyl complexes

5	6	7	8	9	10
$V(CO)_6$	$Cr(CO)_6$	$Mn_2(CO)_{10}$	$Fe(CO)_5$	$Co_2(CO)_8$	$Ni(CO)_4$
			$Fe_2(CO)_9$	$Co_4(CO)_{12}$	
			$Fe_3(CO)_{12}$	$Co_6(CO)_{16}$	
	$Mo(CO)_6$	$Tc_2(CO)_{10}$	$Ru(CO)_5$	$Rh_2(CO)_8$	
		$Tc_3(CO)_{12}$	$Ru_3(CO)_{12}$	$Rh_4(CO)_{12}$	
			$Ru_6(CO)_{18}$	$Rh_6(CO)_{16}$	
	$W(CO)_6$	$Re_2(CO)_{10}$	$Os(CO)_5$	$Ir_4(CO)_{12}$	
			$Os_3(CO)_{12}$	$Ir_6(CO)_{16}$	

There are several possibilities for synthesizing metal carbonyls. The direct reaction of a metal with carbon monoxide is only possible for nickel and iron. Whereas nickel reacts with carbon monoxide at room temperature to give $Ni(CO)_4$ (→ Nickel Compounds) [*13463-39-3*], the formation of $Fe(CO)_5$ [*13463-40-6*] from iron requires elevated temperature and pressure (→ Iron Compounds, Chap. 3.2.). In most other cases, the synthesis involves the reduction of metal compounds (e.g., halides or oxides) in the presence of carbon monoxide. Typical synthetic methods include:

$$Fe + 5\,CO \longrightarrow Fe(CO)_5$$

$$2\,Fe(CO)_5 \xrightarrow[-CO]{h\nu} Fe_2(CO)_9$$

$$Fe(CO)_5 \xrightarrow{OH^-} [HFe(CO)_4]^- \xrightarrow{MnO_2} Fe_3(CO)_{12}$$

$$2\,CoCO_3 \xrightarrow{CO/H_2} Co_2(CO)_8$$

The metal carbonyls are highly reactive complexes. The CO group can be substituted, either thermally or photochemically, by other ligands such as phosphines and olefins:

Metal carbonyls can be converted to anionic carbonyl complexes (carbonyl metallates) by means of the Hieber base reaction. In many cases, the carbonyl metallates are converted to metal carbonyl hydrides by protonation.

$$Fe(CO)_5 \xrightarrow{NaOH} Na[HFe(CO)_4] \xrightarrow{H^+} H_2Fe(CO)_4$$

A further important group of compounds are the carbonyl metal halides, which are formed by reaction of carbonyl complexes with halogens.

$$Fe(CO)_5 + I_2 \longrightarrow Fe(CO)_4I_2 + CO$$

$$Mn_2(CO)_{10} + Cl_2 \longrightarrow 2\,Mn(CO)_5Cl$$

3.1.4. π-Complexes

In addition to a ligand to metal donor bond, π-complexes also exhibit a strong metal to ligand acceptor interaction. The alkene complexes of the transition metals are of major importance because of their roles as intermediates in homogeneous catalysis (cf. Section 3.2). The first alkene complex, the ionic platinum complex $K[(C_2H_4)PtCl_3]$ [*12012-50-9*], was prepared by Zeise in 1827. Alkene complexes can be synthesized by addition of alkenes to coordinatively unsaturated complexes.

$$IrCl(CO)(PPh_3)_2 + R_2C{=}CR_2 \longrightarrow (PPh_3)_2Ir(CO)Cl(R_2C{=}CR_2)$$

Coordinatively saturated complexes can be converted to alkene complexes by ligand displacement.

An important method is the reduction of metal salts or complexes in the presence of alkenes. This method is used to prepare the nickel(0) complexes (cyclododecatriene)-nickel [*39330-67-1*], bis(1,5-cyclooctadiene)-nickel [*1295-35-8*], and tris(ethene)nickel [*50696-82-7*].

In alkyne complexes, the alkynes can act either as monodentate or as bidentate ligands (see

Table 4). The bonding mode is indicated by the C–C bond length of the coordinated alkyne. Monodentate alkynes have C≡C bond lengths of ca. 120 pm, while bidentate alkynes have a C=C bond length of ca. 134 pm. Therefore, bidentate alkynes, for example in $[(PPh_3)_2Pt(Ph_2C_2)]$, are better described as metallacyclopropenes. Alkyne complexes are prepared similarly to alkene complexes, for example, by substitution of carbonyl ligands. Alkyne complexes play an important role as intermediates in homogeneous catalytic oligomerization (see Section 3.2.4) and in the reaction of alkynes with carbon monoxide (Section 3.2.7) or carbon dioxide (Section 3.2.8). Other reactions involving alkyne complexes are the cyclization of alkynes and nitriles to give pyridines, developed by Yamazaki and Bönnemann:

and the Pauson–Khand reaction, in which an alkyne, an alkene, and carbon monoxide react to give a substituted cyclopentenone.

Allyl complexes contain the hydrocarbon ligand C_3H_5, in which the protons may also be replaced by organic substituents. In η^1-allyl complexes, a metal atom is bound to one carbon atom through a σ-bond, while in η^3-allyl complexes three electrons are distributed over three carbon atoms, all of which are bound to the metal center (see Table 4). Allyl complexes are important intermediates in homogeneous catalytic isomerization reactions (see Section 3.2.2) and in the oligomerization and polymerization of 1,3-dienes (see Section 3.2.4). Binary allyl complexes, which can be prepared from transition-metal salts and allyl Grignard reagents, are usually unstable and must therefore be handled at low temperature.

$$NiBr_2 + 2\,C_3H_5MgBr \longrightarrow Ni(C_3H_5)_2 + 2\,MgBr_2$$

Halogen-containing allyl complexes can often be prepared simply from reactions of allyl halides with metal compounds.

Another route to allyl complexes is the addition of metal hydride complexes to 1,3-dienes. An example is the reaction of hydridocobalt tetracarbonyl with butadiene to give a crotyl complex, which can exist in *syn* and *anti* forms.

Although η^5-cyclopentadiene complexes have found no major practical application, they are of interest because of the special electronic properties of the η^5-cyclopentadienyl (Cp) ligand, the wide variety of structures, and their versatile reactivity. Structurally, the simplest Cp complexes are the sandwich complexes, for example, ferrocene [*102-54-5*], $FeCp_2$, which was discovered in 1951. Other examples of the structural variety of Cp complexes are the half-sandwich complexes, triple-decker complexes, MCp_4 complexes, and complexes with bent sandwich structures.

Binary cyclopentadienyl complexes, or metallocenes, are synthesized by reaction of metal salts with a cyclopentadienyl compound (e.g., NaCp or CpMgBr) or with cyclopentadiene, sometimes in the presence of a base.

The Cp ligands of metallocenes readily undergo electrophilic substitution reactions. The chemistry of ferrocene, in particular, has been extensively investigated. Arene complexes are metal complexes of benzene or its derivatives. The most important synthetic route is the reduction of a metal salt by Al and $AlCl_3$ in the presence of an aromatic hydrocarbon. This method was first used by FISCHER and HAFNER for the synthesis of bis(η^6-benzene)chromium [*1271-54-1*]. The intermediate in the reaction is a cationic chromium complex, which is converted to the neutral benzene complex by reduction with sodium dithionite or through disproportionation.

Numerous complexes of benzene, mesitylene, and hexamethylbenzene have been prepared by this method. The synthesis of complexes of polynuclear aromatic hydrocarbons such as naphthalene, anthracene, and phenanthrene requires the use of metal – ligand cocondensation techniques, in which a metal vapor reacts with an arene in the vapor phase, and the resulting complex is condensed on a cooled surface.

Bis(arene) complexes undergo a wide range of reactions. The aromatic ligands can be substituted via lithiation reactions and displaced by other arene ligands. For example, the naphthalene ligands in bis(naphthalene)chromium [*33085-81-3*] undergo partial exchange with benzene. The arene complexes are, however, of no industrial importance.

3.2. Transition-Metal Catalysis

Homogeneous transition-metal catalysis exploits the versatile reactivity of transition-metal complexes for the synthesis of organic molecules. The critical intermediates in the catalytic cycles are mostly the organo transition metal complexes described in Section 3.1.

The advantage of homogeneous catalysis over heterogeneous catalysis is that the selectivity of the reaction can be controlled by appropriate choice of the ligands on the catalytic metal center. Organometallic catalysis often allows the synthesis of organic compounds that are otherwise only accessible through complex multistep syntheses. Also, homogeneously catalyzed enantioselective reactions with high optical yields are carried out industrially. Noteworthy is that homogeneous catalysis can often be achieved under mild conditions of temperature and pressure. A drawback to these processes is the expense of the required noble metals, for example, rhodium (see Table 6). In spite of the high cost of these metals, many bulk chemicals, such as butyraldehyde and acetic acid, are produced by means of homogeneous transition-metal catalysis at costs of a few cents per mole. This is possible when a large quantity of product is formed for each mole of catalyst; that is, when the reaction has a high turn-over rate. Furthermore, there are many methods by which the catalyst can be recovered almost quantitatively after the reaction, including precipitation, reverse osmosis, immobilization on carrier materials, and reaction in two-phase liquid – liquid systems [95–185].

3.2.1. Catalytic Elementary Reactions [186–233]

Fundamentally speaking, a homogeneous catalytic cycle can be divided into the following steps: formation of the active species (I), coor-

dination of the reactants at the metal center (II), formation of the product (III), and elimination of the product (IV) with reformation of the initial catalytic species.

The first step involves in situ formation of the catalytically active species ML_{n-x} from the starting complex ML_n. The active species possesses vacant coordination sites, which is a prerequisite for coordination of the reactants A and B. The active species is usually formed by ligand dissociation; that is, by elimination of Lewis acids (e.g., protons) or Lewis bases (e.g., phosphines).

In the second step, one or more reactants bind to the metal center. This can occur either by ligand association, in which, for example, alkenes, alkynes, or carbon monoxide add to the metal center, or by oxidative addition, in which molecules such as H – H, H – X, or R – X are cleaved and the two fragments bind to the metal by σ-bonds. In the latter case, both the coordination number and the oxidation state of the metal increase by two. An example of oxidative addition is the addition of dihydrogen to the square-planar complex $[Ir(CO)(PPh_3)_2Cl]$ (Vaska's complex). The addition of H_2 to the Ir(I) complex occurs in a synchronous bimolecular reaction, giving an octahedral Ir(III) complex with *cis* hydride ligands.

The third step of the catalytic cycle involves bond-forming reactions between the reactants bound to the metal center. Insertion reactions, in which for example ligand B inserts into the metal – A bond are often observed. Examples include the insertion of carbon monoxide into metal – alkyl bonds to give acyl complexes, the insertion of ethylene into metal hydrogen bonds to give ethyl complexes, and the synthesis of crotyl complexes of cobalt through insertion of butadiene into cobalt – hydrogen bonds.

In some cases insertion reactions are reversible; the reverse reaction is termed extrusion. Also noteworthy are multiple insertion reactions. For example, two CO molecules can insert into a metal – alkyl or metal – aryl bond, offering a catalytic route to α-keto carboxylic acids (see Section 3.2.7).

Another important bond-forming reaction is oxidative coupling, which is of particular importance in the dimerization of alkynes, alkenes, and 1,3-dienes (see Section 3.2.4).

A special case of oxidative coupling is the coupling of metal carbenes with alkenes to give a metallacyclobutane. This has been discussed as the crucial step in the metathesis reaction (Section 3.2.5).

Table 7. Elementary catalytic steps

Elementary catalytic step	General equation	Importance in the catalytic cycle
Association → Dissociation ←	$L_nM + X \rightleftharpoons L_nMX$	Addition and cleavage (Steps I, II, IV)
Oxidative addition → Reductive elimination ←	$L_nM + X-Y \rightleftharpoons L_nM{<}^{X}_{Y}$	
Insertion → Extrusion ←	$L_nMX + Y \rightleftharpoons L_nMYX$	Bond formation (step III)
Oxidative coupling → Reductive cleavage ←	$L_nM{<}^{X}_{Y} \rightleftharpoons L_nM{<}^{X}_{Y}$	

The reverse of oxidative coupling is known as reductive cleavage.

The fourth step of the cycle involves elimination of the product. If the product is bound to the metal through a η^2-bond, this can occur by ligand dissociation.

Often, the product is released through reductive elimination, the reverse of oxidative addition. Some examples are as follows:

The β-elimination of hydrogen from alkyl complexes, which can be regarded as the reverse of alkene insertion into M–H bonds, leads to formation of alkenes. This reaction is an important chain-terminating step in oligomerization

reactions. Table 7 gives a survey of the various catalytic elementary reactions.

The following Sections introduce those homogeneous catalytic reactions which have gained industrial importance. These include isomerization, hydrogenation, oligomerization and polymerization, metathesis, oxidation, and functionalization with molecules such as carbon monoxide. The most important substrates for these reactions are those which can associate with metal complexes and those which can undergo oxidative addition to a metal center; in particular alkenes, alkynes, carbon monoxide, and hydrogen. The wide variety of reactions and the possibility of controlling them by appropriate choice of catalyst allow the synthesis of a wide range of low and high molecular mass hydrocarbons and mono- and polyfunctional compounds. Homogeneous catalysis is used for the synthesis of bulk chemicals such as acetaldehyde, acetic acid, oxoalcohols, α-olefins, and high-density polyethylene and, increasingly, for fine chemicals, including pharmaceuticals, flavors, fragrances, and special agrochemicals. Although organometallic catalysis has a relatively short history, it is already of considerable importance in industrial chemistry. Industrial processes based on homogeneous catalysis reached a turnover of $\$23 \times 10^9$ in the United States in 1990, and new applications can be expected in electronics, metal-containing pharmaceuticals, and specialty polymers.

3.2.2. Isomerization [234–256]

Transition-metal complexes can catalyze the isomerization of double-bond systems such as alkenes, dienes, and allyl compounds and skeletal rearrangements of cyclic aliphatic compounds. Transition-metal hydride complexes of general formula L_nMH, which may also be formed in situ from ML_n and hydrogen, are often used as homogeneous isomerization catalysts.

The driving force for isomerization is the formation of thermodynamically more stable iso-

mers. Isomerization is an equilibrium reaction that is strongly influenced by the reaction temperature. At higher temperature, the proportion of the thermodynamically less stable isomer increases. In unsaturated compounds, the stability of the individual structural units generally follows the following rules:

1) Inner alkenes are more stable than terminal alkenes

2) Highly branched alkenes are more stable than less branched alkenes

3) Conjugated dienes are more stable than unconjugated dienes

$$R-CH=CH-CH=CH-R > R-CH=CH-(CH_2)_n-CH=CH-R$$

4) In olefins with functional groups, those having conjugated multiple bonds are particularly stable:

$$R-CH_2-CH=CH-X > R-CH=CH-CH_2-X$$
$$(X = COOH, COOR, CN, Ph, \ldots)$$

Two mechanisms are discussed in alkene isomerization. In the hydride mechanism, the alkene adds to the transition-metal hydride to give an η^2-alkene complex, which rearranges to give a σ-alkyl complex. Elimination of the product olefin then leads to reformation of the initial hydride complex.

In the allyl mechanism, the transition metal removes a proton adjacent to the double bond to form an η^3-allyl complex as isomerization intermediate.

Numerous complexes of metals of groups vier, 6, 8, 9, and 10 can be used as isomerization catalysts. Rhodium chloride, rhodium chloro complexes, iron carbonyls, and palladium and titanium complexes are most widely used in practice.

Alkene Isomerization. 1-Hexene can be converted to 2- and 3-hexene in the presence of iron carbonyls:

Rhodium trichloride [*10049-07-7*] is an efficient catalyst for the isomerization of exocyclic enones into endocyclic enones. This allows the synthesis of 2-substituted cyclopentenones:

Sesquiterpene-α-methylene-γ-butyrolactones such as damsin [*1216-42-8*] have received much attention because of their antitumor activity. A selective isomerization of damsin [*1216-42-8*] to isodamsin [*17081-89-9*] can be achieved with the rhodium hydride complex [$(PPh_3)_2RhH_2Cl$] [*12119-41-4*]. Since Wilkinson's catalyst [$(PPh_3)_3RhCl$] [*14694-95-2*] is inactive in this isomerization, the reaction probably occurs through addition of Rh – H to the exocyclic double bond:

Damsin Isodamsin

A new synthesis of L-menthol [*2216-51-5*] is based on the selective isomerization of nerylamine to give a specific enamine isomer. The catalyst is a complex of rhodium with the (+)-isomer of the ligand BINAP:

Nerylamine Enamine L-Menthol

Alkyne Isomerization. Alkynes can be converted to the corresponding allenes by means of manganese complexes:

A process that has found practical application is the vanadium-catalyzed isomerization of dehydrolinalool to give citral. Whereas alkyl vanadate catalysts require temperatures above 160 °C, oxovanadium(IV) acetylacetonate [*3153-26-2*] is active at room temperature:

Diene Isomerization. 1,5-Cyclooctadiene [*1552-12-1*] is converted to the thermodynamically more stable 1,3-isomer by iron pentacarbonyl [*13463-40-6*]:

The same reaction can be achieved with hydrido iridium catalysts.

Skeletal Isomerization of Ring Molecules. Molecules with small rings (e.g., cyclopropanes, cyclobutanes, epoxides) can undergo isomerization of their molecular frameworks in the presence of transition-metal catalysts. Typical examples are the isomerization of bicyclo[2.1.0]-pentane [*185-94-4*] to cyclopentene with $[Rh(CO)_2Cl]_2$ [*14523-22-9*], and the isomerization of cyclohexene epoxide [*286-20-4*] to cyclohexanone [*108-94-1*]:

Also of interest is the rearrangement of cubane [*277-10-1*] to give cyclooctatetraene [*629-20-9*] (COT) and of quadricyclane [*278-06-8*] to form norbornadiene [*121-46-0*]. Although both of these isomerizations are forbidden by the Woodward–Hoffmann rules, they can be carried out in the presence of transition metals.

Homogeneous isomerization has found only limited use in industry. However, it does play an important role as a side reaction in hydroformylation, hydrocarboxylation, and addition reactions of alkenes.

3.2.3. Hydrogenation [257–287] (see also → Hydrogenation and Dehydrogenation)

The hydrogenation of alkenes, dienes, and alkynes can be carried out with homogeneous transition-metal catalysts. Typical hydrogenation catalysts are H_2IrCl_6 [*10025-83-9*], $[(PPh_3)_2IrCl(CO)]$ [*14871-41-1*], $[HCo(CO)_4]$ [*16842-03-8*], and $[(PPh_3)_2(CO)_2RuCl_2]$ [*14564-35-3*]. One of the most widely used catalysts is Wilkinson's catalyst $[(PPh_3)_3RhCl]$, which in many cases allows the reaction to be carried out under mild conditions. A simplified reaction scheme for a hydrogenation reaction with Wilkinson's catalyst is as follows:

Oxidative addition of hydrogen gives a dihydrido rhodium (III) complex, which through dissociation of a phosphine ligand provides a vacant coordination site for bonding of an alkene. An insertion step then gives a hydrido alkyl rhodium complex, which upon elimination of an alkane and recomplexation of the phosphine gives the starting complex.

Whereas $[(PPh_3)_3RhCl]$ catalyzes the hydrogenation of terminal and inner alkenes, the hydride complex $[(PPh_3)_3Rh(CO)H]$ [*22172-51-6*] hydrogenates only terminal double bonds; it is also somewhat less reactive. The carbonyl chloro complex *trans*-$[(PPh_3)_3Rh(CO)Cl]$ [*13938-94-8*] catalyzes the hydrogenation of ethene and propene, albeit with only slow rates of reaction. In contrast, the corresponding iridium complex *trans*-$[(PPh_3)_3Ir(CO)Cl]$ is considerably more reactive. Also noteworthy is the high activity of many cationic catalysts; for example, complexes of the type $[L_2Rh(THF)_2]^+$.

Of particular interest is asymmetric hydrogenation, in which prochiral unsaturated substrates are converted to chiral products by means of transition-metal catalysts with optically active diphosphine ligands such as DIOP, CHIRAPHOS, NORPHOS, and DIPAMP:

Some commercial applications of asymmetric hydrogenation already exist, the best known being the Monsanto process for the production of the chiral amino acid 3,4-dihydroxyphenylalanine [*63-84-3*], which in its L-form (L-Dopa) [*59-92-7*] is used for the treatment of Parkinson's disease.

BINAP complexes of ruthenium have proved to be particularly effective catalysts for asymmetric hydrogenation of β,γ-unsaturated carboxylic acids, allyl alcohols, enamides, α-aminoketones, and substituted acrylic acids. The synthesis of the sweetener Aspartame [*22839-47-0*] (the methyl ester of L-aspartyl-L-phenylalanine) also involves asymmetric hydrogenation.

The high selectivity of homogeneous hydrogenation catalysts compared to classical heterogeneous catalysts is demonstrated by two other industrial processes. The fragrance linalool [*22564-99-4*] is produced by BASF in a multistep synthesis, in the last step of which the triple bond of dehydrolinalool is selectively hydrogenated.

Merck has developed a synthesis of Ivermectin [*70288-86-7*], which is used in the third world for the treatment of worm infestations. Ivermectin is prepared from Avermectin B1 by selective hydrogenation of the double bond in the C22 position (arrow). Although four other

C=C double bonds are present in the molecule, Wilkinson's catalyst leads to hydrogenation exclusively in the desired position.

As shown by the above-mentioned examples, homogeneous hydrogenation is gaining increasing importance for the synthesis of pharmaceuticals and fine chemicals.

3.2.4. Carbon – Carbon Bond Formation [288–373]

This section deals with linear and cyclic oligomerization, telomerization, polymerization, and vinylogation. Carbon – carbon bond formation by metathesis, reactions of CO, or addition of HCN or CO_2 to alkenes are described in Sections 3.2.5, 3.2.7, and 3.2.8, respectively.

The oligomerization of alkenes leads to linear or branched high molecular mass alkenes, which are important for the production of detergents, plasticizers, and fine chemicals (see also → Hydrocarbons). Two mechanisms have been discussed: the hydride mechanism and the metallacycle mechanism. In the former, the catalytically active species is a metal hydride complex, into whose M – H bond an alkene inserts. Further insertions of alkene molecules into the resulting metal – carbon bond lead to long-chain metal alkyls. The reaction is terminted by β-hydrogen elimination with liberation of the oligomer and reformation of the metal hydride (see figure at bottom).

An example of the metallacycle mechanism is the dimerization of ethene to give butene. A bis(ethene) complex forms a metallacyclopentane, which rearranges to a butene complex by a hydrogen shift reaction.

Numerous catalysts for ethene oligomerization have been investigated. An important group are the Ziegler – Natta catalysts, which are prepared from a transition-metal component and an aluminum alkyl. The most important transition metals for these catalysts are titanium, zirconium, cobalt, and nickel. Titanium and zirconium are used mostly in the form of their alkoxides or halides, and cobalt and nickel as acetylacetonates or allyl complexes. The catalytically active species are adducts of the transition-metal compound and the aluminum component. An example is the reaction of titanium tetrachloride with ethylaluminum dichloride, which gives a complex with a free coordination site for the binding of an olefin.

Apart from Ziegler–Natta catalysts, there are other metal compounds that catalyze the oligomerization of alkenes without activation by aluminum alkyls. These include rhodium trichloride [*10049-07-7*], palladium dichloride [*7647-10-1*], ruthenium trichloride [*10049-08-8*], and the cobalt dinitrogen complex $[CoH(N_2)(PPh_3)_3]$ [*16920-54-0*]. Of greatest industrial importance, however, are the nickel complexes of phosphorus/oxygen chelates that are used in the SHOP process (Shell) for the oligomerization of ethylene to α-olefins (→ Hydrocarbons). The catalytically active species is a nickel hydride, which is formed as shown for the following nickel phosphorus ylide complex:

Although higher olefins such as propene or butene can also be oligomerized, the reactions often lead to formation of branched products.

Also of industrial interest is the oligomerization of alkenes with functional groups, such as acrylonitrile, styrene, and acrylates. Linear dimerization of acrylonitrile gives 1,4-dicyanobutenes, which can be used as precursors for nylon 66. The hydrodimerization of acrylonitrile leads directly to adiponitrile [*111-69-3*].

$$2\,CH_2{=}CH{-}CN + H_2 \longrightarrow NC{-}(CH_2)_4{-}CN$$

Also of importance is the linear coupling of methyl acrylate [*96-33-3*], for which $RhCl_3$, $RuCl_3$, and $[PdCl_2(PhCN)_2]$ [*14220-64-5*] were originally used as catalysts. Since then, considerably more selective catalysts have been developed, for example, methallyl cyclooctadiene palladium tetrafluoroborate [*46135-01-7*] and $[Pd(\eta^3\text{-}C_3H_5)(PMe_3)]BF_4$.

Alkynes also undergo oligomerization reactions. Linear dimerization of acetylene gives vinyl acetylene [*689-97-4*], which was formerly an important precursor for chloroprene. A typical catalyst is CuCl in ammonium chloride solution.

$$2\,HC{\equiv}CH \xrightarrow{[Cu]} HC{\equiv}C{-}CH{=}CH_2$$

Cyclic oligomerization of alkynes is, however, more common than linear oligomerization.

Cyclotrimerization of alkynes affords benzene derivatives, while cyclotetramerization yields derivatives of cyclooctatetraene.

Cyclic alkyne coupling reactions have been used by VOLLHARDT for the synthesis of polycyclic systems, a typical reaction being the coupling of an α,ω-diyne with an alkyne.

An important catalyst for this reaction is $[CpCo(CO)_2]$ [*12078-23-8*]. This synthetic method has been used for elegant syntheses of steroids, such as the female sex hormone estrogen [*53-16-7*].

1,3-Dienes can also be oligomerized, 1,3-butadiene [*106-99-0*] being particularly reactive. Cyclic oligomerization of butadiene gives isomers having various ring sizes.

The dimer 1,5-cyclooctadiene [*1552-12-1*] is industrially important. It is synthesized by means of nickel catalysts that contain a sterically demanding ligand. The reduction of nickel bis(acetylacetonate) with $AlEt_2(OEt)$ in the presence of the ligand gives a complex that catalyzes the formation of 1,5-cyclooctadiene in almost quantitative yield under mild conditions. Mechanistically, the reaction is assumed to occur by coupling of two butadiene molecules to give a bis(allyl)nickel complex, whereby the ligand L hinders the coordination of a third butadiene molecule.

1,5-Cyclooctadiene is a versatile product. Complete hydrogenation and subsequent oxidation cleaves the molecule to give suberic acid [*505-48-6*]. Metathesis with ethene gives 1,5-hexadiene [*592-42-7*], and selective hydrogenation affords cyclooctene [*931-87-3*], which can be converted to a polyoctenamer by homometathesis, or to 1,9-decadiene [*1647-16-1*] by ethenolysis. Cyclotrimerization of butadiene is carried out industrially in the presence of a Ziegler – Natta catalyst, prepared from $TiCl_4$ and $Al_2Cl_3Et_3$, to give *cis,trans,trans*-1,5,9-cyclododecatriene [*706-31-0*]. Cyclotrimerization with nickel catalysts requires the use of naked nickel complexes (i.e., without phosphorus ligands). The mechanism can be summarized schematically as follows:

Nickel catalysts give the all-trans isomer. Du Pont (United States) and Hüls (now Degussa Hüls) (Federal Republic of Germany) produce cyclododecatriene as a precursor for nylon fibers. Hydrogenation gives cyclododecane, which can be oxidized to dodecane dicarboxylic acid [*693-23-2*]. Cyclododecane can also be converted to a C_{12} lactam, which is used for the synthesis of nylon 12.

Also of industrial importance are cooligomerization reactions, for example, of dienes and alkenes. An important example is the synthesis of *trans*-1,4-hexadiene [*7319-00-8*], which has been produced by Du Pont since 1963 and is used for production of EPDM elastomers (Nordel). In the copolymerization of the diene with ethene and propene to give EPDM, the terminal double bond of the 1,4-hexadiene reacts, while the less reactive inner double bond can be used for further polymerization reactions.

The synthesis of *trans*-1,4-hexadiene occurs by rhodium-catalyzed cooligomerization of ethene and butadiene. The starting material is rhodium trichloride, which is converted to a rhodium hydride complex. Addition of butadiene then gives an η^3-crotyl complex, which undergoes coordination and insertion of an ethene molecule. Subsequent coordination of butadiene then leads to elimination of *trans*-1,4-hexadiene.

The reaction can also be carried out with Ziegler – Natta catalysts such as $NiCl_2(PPh_3)_2$/*i*-$BuAlCl_2$. The use of cobalt or iron catalysts results in formation of *cis*-1,4-hexadiene [*7318-67-4*].

Another commercially important oligomer is ethylidenenorbornene [*16219-75-3*], which can be prepared from cyclopentadiene and butadiene. An uncatalyzed Diels – Alder reaction gives 5-vinylnorbornene [*3048-64-4*], which can be converted to ethylidenenorbornene by, for example, titanium Ziegler catalysts. An alternative synthesis is the nickel-catalyzed cooligomerization of norbornadiene and ethene. Like 1,4-hexadiene, ethylidenenorbornene is used in EPDM elastomers.

An interesting possibility is the ability to perform asymmetric cooligomerization reactions. For example, the cooligomerization of norbornene [*498-66-8*] with ethene in the presence of metal complexes containing optically active phosphine ligands leads to selective formation of a single enantiomer. Dimenthyl alkyl phos-

phines are effective optically active ligands for this reaction:

Telomerization is a C – C bond-forming reaction that is closely related to oligomerization. Telomerization is the dimerization of a 1,3-diene with simultaneous addition of a nucleophile HX. Although in principle different isomers can result, their formation is controlled by the catalyst:

The most important telomerization catalysts are palladium complexes, such as $[Pd(PPh_3)_2(MA)]$ [*17830-50-1*] (MA = maleic anhydride), $[Pd(OAc)(C_3H_5)_2]_2$ [*12084-71-8*], and combinations of palladium acetate or palladium acetylacetonate with phosphines or phosphites. Whereas nickel complexes also give high yields of telomers, only in a few cases are platinum and rhodium active in telomerization.

A wide range of compounds can serve as nucleophiles in these reactions, including water, alcohols, silanols, carboxylic acids, primary and secondary amines, β-diketones, malonates, β-ketoesters, and nitroalkanes. Telomerization has yet to gain major industrial importance. Nevertheless, the multiple functionality of the telomers makes them excellent starting materials for the synthesis of complex natural products. Butadiene and acetic acid undergo telomerization with high selectivity to give an octadienyl acetate, which can be converted in five steps to dihydrojasmone [*1128-08-1*].

The telomer 3-hydroxy-1,7-octadiene can be dehydrated to give the corresponding ketone, which is an important building block for the synthesis of steroid systems.

The telomerization of nitromethane with butadiene leads to binding of two octadienyl chains to the carbon atom of the nitroalkane. The resulting molecule can be used for the synthesis of *cis*-civetone [*542-46-1*].

Polymerization of alkenes (→ Polyolefins) is a major field of application for transition-metal catalysis. For example, isotactic polypropylene is produced with titanium catalysts. Up to now heterogeneous catalysts have mainly been used for this purpose. These include γ-$TiCl_3$, prepared from $TiCl_4$ and $AlEt_3$; titanium chloride on a magnesium chloride carrier; and δ-$TiCl_3$.

However, homogeneous catalysts are used preferentially in some areas of polymer technology. For example, high-density polyethylene is produced in the presence of a homogeneous catalyst prepared from $TiCl_4$ and aluminum alkyls. A newly developed, highly active catalyst for the synthesis of linear polyethylene is a combination of $[Cp_2ZrCl_2]$ [*1291-32-3*] and methyl aluminoxane [*90330-46-4*]; the yield is 10^6 kg polyethylene per hour per mole of zirconium complex. Isotactic polypropylene can also be produced by homogeneous catalysis, for example, with ethylene bis(indenyl) zirconium dichloride [*112243-78-4*] and methylaluminoxane.

EDPM polymers are also produced by homogeneous catalysis. The catalysts are presumably alkyl vanadium (III) complexes, which are formed in situ from vanadium compounds such as $VOCl_3$ [*7727-18-6*] or VCl_4 [*7632-51-1*] and aluminum alkyls. The resulting terpolymers are used as highly ozone resistant elastomers. *Cis*-1,4-polybutadiene [*9003-17-2*] is another polymer that is readily accessible by transition-metal catalysis. In the Phillips pro-

cess, Ziegler catalysts prepared from titanium halides and aluminum alkyls are used, while the Goodrich process employs catalysts that are prepared from cobalt salts and alkylaluminum halides. Nickel-based catalysts exhibit similar reactivity and give *cis*-1,4-polybutadiene with selectivities greater than 90 %. A mechanistic explanation for the high cis selectivity is as follows:

The growing polymer chain is bound to the catalytic metal center M by an η^3-allyl bond. Butadiene coordinates to the metal as a chelate and undergoes C – C coupling with the terminal carbon atom of the allyl group, simultaneously forming a new η^3-allyl bond. The η^3-allyl bonding means that each chain extension step forms only a cis double bond.

Further use of organometallic catalysts in polymer chemistry can be expected in the future. The synthesis of polyacetylene [*25067-58-7*], which has applications in electronics and energy storage, and of specialized methacrylate polymers for use in fiber optics have been extensively investigated.

Finally, a few examples of the use of C – C bond-forming reactions in the synthesis of fine chemicals are given below. An important class of reactions are metal-catalyzed cyclopropanations, in which alkyl diazonium acetates react with particular unsaturated compounds to give novel pyrethroid insecticides.

The regio- and enantioselectivity of the reaction can be controlled by choice of the metal catalyst, usually a cobalt, rhodium, or copper complex. Mechanistically, it is assumed that the metal and the diazo compound first form a carbene complex, which reacts with the alkene to give a metallacyclobutane. The cyclopropane derivative is formed by reductive elimination, reforming the catalyst.

Also of importance is the vinylogation of alkenes, for which vinyl halides are used as vinylogating agents, and palladium complexes, prepared in situ from $Pd(OAc)_2$, PPh_3, and NEt_3, as catalysts.

3.2.5. Metathesis [374–404]

Metathesis is formally the exchange of alkylidene groups between two alkenes.

Typical heterogeneous metathesis catalysts are WO_3 [*1314-35-8*] on SiO_2, and Re_2O_7 [*1314-68-7*] on Al_2O_3, while an important homogeneous catalytic system is WCl_6 – EtOH –

R_2AlCl. The reactive intermediates are assumed to be carbene complexes.

The formation of the metal carbene in the catalytic system $WCl_6 - Me_2AlCl$ is believed to occur as follows:

The oldest industrial metathesis process, the Phillips triolefin process, in which 2 mol of propene is converted to ethene and 2-butene, was brought on-line in 1966.

However, the 50×10^3 t/a Phillips plant in Canada ceased production in 1972 because of the changed situation in the olefin market. In the meantime, the reverse reaction, the synthesis of propene from ethene and 2-butene, was taken up by the Atlantic Richfield Corp. In the first step ethene is dimerized to give 2-butene, which is then metathesized with an excess of ethene in the presence of $Re_2O_7 - Al_2O_3$ catalysts. This reaction allows the mixture of lower alkenes formed in the naphtha pyrolysis to be altered to correspond to prevailing market requirements.

The largest use of metathesis is currently the SHOP process (Shell), in which ethylene is oligomerized to give long-chain α-olefins. Undesired low molecular mass olefins ($<C_{10}$) and high molecular mass alkenes ($>C_{20}$) can be converted by metathesis to $C_{10} - C_{14}$ inner alkenes after an isomerization step. The terminal and inner alkenes produced in the SHOP process are used mainly for the production of detergents, plasticizer alcohols, synthetic lubricants, and LLDPE. Total world SHOP plant capacity is currently being increased to over 800×10^3 t/a. Another major application of metathesis is the synthesis of polyalkenamers by metathesis of cyclic alkenes. The initial cyclic molecule undergoes ring opening and is converted stepwise to larger and larger rings and, finally, polymers. This reaction is also called ring-opening metathesis polymerization (Romp).

The first industrial application of ring-opening metathesis dates from 1976. In a 5000 t/a plant of CdF-Chimie (France), norbornene is converted to polynorbornene [*25038-76-0*] (Norsorex), presumably by means of tungsten catalysts.

The metathesis of cyclooctene to give a polyoctenamer has been carried out by Hüls since 1980. The product is sold under the trade name Vestenamer 8012.

The metathesis of dicyclopentadiene to give the polymer Metton has been operated in Canada by Hercules since 1985.

Less important industrial applications of metathesis include the Phillips neohexene process and the Shell Feast process (→ Hydrocarbons, Chap. 2.2.3.). The neohexene is formed by metathesis of 2,4,4-trimethyl-2-pentene [*558-37-2*] and ethene.

In the Feast process, cycloolefins and ethene are converted to α,ω-dienes, which are otherwise industrially inaccessible. Starting material for the Feast process is 1,5-cyclooctadiene, which can be produced by cyclodimerization of butadiene.

3.2.6. Oxidation [405–435]

In the Wacker–Hoechst process (→ Acetaldehyde, Chap. 4.3.1.), ethene chloro complexes of palladium (II) are decomposed by water to give acetaldehyde and palladium(0). The oxidation of Pd(0) back to Pd(II) can be carried out with air, whereby the use of a Cu(I)/Cu(II) couple allows the reaction to be carried out catalytically. The sum of all the reactions involved is the reaction of ethene and oxygen to give acetaldehyde.

$$
\begin{array}{lll}
1)\ C_2H_4 + PdCl_2 + H_2O & \longrightarrow & CH_3CHO + Pd(0) + 2\,HCl \\
2)\ Pd(0) + 2\,CuCl_2 & \longrightarrow & PdCl_2 + 2\,CuCl \\
3)\ 2\,CuCl + 2\,HCl + 1/2\,O_2 & \longrightarrow & 2\,CuCl_2 + H_2O \\
\hline
\Sigma\quad C_2H_4 + 1/2\,O_2 & \longrightarrow & CH_3CHO
\end{array}
$$

When the reaction is carried out with terminal or inner alkenes, ketones are obtained. For example, propene can be converted to acetone. In the mechanism for acetaldehyde formation, it is assumed that first ethene and then water adds to the metal center. A hydroxyethyl complex is then formed by oxypalladation, which, after rearranging to a hydrido vinylalcohol complex, releases acetaldehyde.

The reaction is versatile in that solvents other than water can be used. Oxidation in alcohols yields the corresponding vinyl ethers, while reaction in acetic acid affords vinyl acetate. A large proportion of the acetaldehyde produced by the Wacker–Hoechst process is oxidized to acetic acid or acetic anhydride by means of manganese, cobalt, or copper salts.

Another oxidation reaction of olefins is epoxidation, which is carried out on an industrial scale by reaction of ethene with oxygen on heterogeneous silver catalysts (→ Ethylene Oxide). Homogeneous epoxidation is also used industrially. For example, selective epoxidation of olefins with hydroperoxides can be catalyzed by molybdenum or vanadium compounds.

This reaction was developed further by Halcon for the production of propene oxide, in which *tert*-butyl hydroperoxide or ethylbenzene hydroperoxide is used as the oxidant for propene. A simplified scheme for the reaction with a molybdenum catalyst is as follows:

Stereoselective epoxidation is used industrially for the synthesis of fine chemicals. An example is the insect pheromone (+)-disparlure

[*54910-51-9*], which is used against the gypsy moth, a leaf-feeding insect that causes extensive damage to trees in the United States. The synthesis starts from the allyl alcohol *Z*-2-tridecenol, which is converted to the desired epoxide in 95 % enantiomeric purity by titanium alkoxides, D-(−)-diethyl tartrate, and *tert*-butyl hydroperoxide.

Propranolol [*13071-11-9*] is used for the treatment of cardiac disease and high blood pressure. In the first step of its synthesis, allyl alcohol is epoxidized with *tert*-butyl hydroperoxide, affording the corresponding glycidol. A titanium complex of diethyl tartrate is used as catalyst, whereby the use of (+)- or (−)-tartrate leads to formation of the corresponding glycidol isomer.

Also of major importance is the homogeneous catalytic oxidation of alkanes and alkyl aromatics. The radical chain reactions are initiated by cobalt or manganese ions. Therefore, unlike olefin oxidation or epoxidation, the oxidation of alkanes and alkyl aromatics does not directly involve the transition-metal complex.

Linear short-chain alkanes, in particular butane, can be converted to acetic acid by liquid-phase oxidation with cobalt acetate as catalyst. The reaction is, however, unselective, and has a maximum yield of ca. 50 %. A similar process is used to oxidize cyclohexane to give a mixture of cyclohexanone [*108-94-1*] and cyclohexanol [*108-93-0*], which can be converted in a second step to adipic acid [*124-04-9*].

p-Xylene is oxidized industrially to give terephthalic acid [*100-21-0*] or dimethyl terephthalate [*120-61-6*]. In order to convert both methyl groups of *p*-xylene to carboxyl groups, either bromide ions are added to the metal catalyst (Amoco process) or an indirect route via methyl toluate is used. It is assumed that the Co(II) or Mn(II) catalysts used are oxidized by the hydroperoxides to give M(III) ions, which can then initiate the oxidation by extraction of a benzylic hydrogen atom. The oxidation of alkyl aromatics is also used for the synthesis of fine chemicals. For example, oxidation of *p*-*tert*-butyltoluene with a cobalt bromide catalyst affords the corresponding aldehyde, which can be converted to the fragrance lilial [*80-54-6*] by aldol condensation with propionaldehyde followed by selective hydrogenation.

3.2.7. Reactions with Carbon Monoxide [436–468]

Of the many reactions of carbon monoxide, only the important transition-metal catalyzed reactions with hydrogen, alkynes, alkenes, and alcohols are described here.

The synthesis of methanol is the most important of the reactions with hydrogen; it is carried out heterogeneously with zinc, chromium, or copper oxide catalysts. The mixture of carbon monoxide and hydrogen (synthesis gas) is also the starting material for the Fischer – Tropsch reactions. In the presence of heterogeneous cobalt or iron catalysts, these reactions can be used for the production of alkane mixtures that can be used as fuels. Currently, this process is carried out on an industrial scale in South Africa, where cheap coal is used as the source of the synthesis gas. More recent research on Fischer – Tropsch chemistry has the aim of controlling the reac-

tions by means of the catalyst to give other products such as short-chain olefins, long-chain α-olefins, and alcohols. Homogeneous reactions of hydrogen and carbon monoxide have also been extensively investigated. An interesting result is the rhodium-catalyzed synthesis of ethylene glycol, albeit at pressures above 100 MPa.

The reactions of carbon monoxide with alkynes are largely based on the work of Reppe. For example, acetylene, carbon monoxide, and water can be converted to acrylic acid with the catalyst $Ni(CO)_4$ [*13463-39-3*]. The reaction is regarded as the hydrocarboxylation of an alkyne. Instead of water, other molecules of general formula HX can be used. In the reactions with alcohols (hydroesterification of alkynes), acrylates are formed, which are used for production of polyacrylates. The reaction involves the formation of a nickel hydride species, which undergoes insertion of acetylene. Subsequent insertion of carbon monoxide and reaction with the alcohol gives the acrylate with reformation of the nickel hydride complex (see figure at top of page).

The reactions of alkenes with carbon monoxide also include hydrocarboxylation and hydroesterification reactions, in which saturated carboxylic acids or their esters are formed; for example, propanoic acid from ethylene. In the presence of iodine-modified nickel carbonyl catalysts, the reactions occur at 190 °C and 10 MPa CO pressure. Longer-chain alkenes always give mixtures of carboxylic acids because the carbon monoxide can attack at various carbon atoms of the alkene due to possible isomerization of the double bond.

BASF has further developed the hydroesterification of butadiene to give dimethyl adipate [*627-93-0*]. The intermediate in the reaction is methyl 3-pentenoate. The two reaction steps, which occur at different CO pressures, require a catalyst prepared from $Co_2(CO)_8$ [*10210-68-1*] and a nitrogen base (e.g., pyridine).

By far the most important reaction of carbon monoxide with alkenes is hydroformylation (→ Oxo Synthesis), discovered by Roelen at Ruhrchemie, in which, for instance, ethene and synthesis gas in the presence of a cobalt carbonyl catalyst give propionaldehyde. Currently, ca. 5×10^6 t/a of C_3-C_{19} oxo products are produced worldwide. The primary products of the reactions are aldehydes, which are mostly converted to other products, principally alcohols. The mechanism of cobalt-catalyzed hydroformylation is believed to involve a hydridocobalt carbonyl as catalytically active species. Insertion of olefin and carbon monoxide gives an acyl complex that is hydrogenated, forming the aldehyde.

The oxo synthesis catalysts have been developed over a time-span of 50 years. Classical hydroformylation with unmodified cobalt catalysts is performed at 150 °C and 20 – 30 MPa. The aldehyde yield is 90 %, and the ratio of linear to branched (*n*/*iso*) aldehydes is 3 : 1. Modification of the cobalt catalysts, in particular by using phosphine ligands, allowed the reaction pressure to be reduced to 10 MPa and improved the *n*/*iso* ratio to 7 : 1. A major development was the use of rhodium catalysts, which are ca. 1000 times more active. Since the reaction can be carried out at 1 – 2 MPa, it is termed low-pressure oxo synthesis (LPO process). It gives a yield of aldehyde of 98 % and good selectivity for formation of the desired *n*-aldehydes. Use of the catalyst $[HRh(CO)(PPh_3)_3]$ gives an *n*/*iso* ratio of >10 : 1. A further development is the use of rhodium catalysts with water-soluble phosphine ligands such as tris(*m*-sulfonato)triphenylphosphine. In this process, jointly developed by Rhône-Poulenc and Ruhrchemie, the reaction is carried out in a two-phase liquid – liquid system, which simplifies separation of the organic product from the aqueous catalyst phase and thus minimizes catalyst losses. Hydroformylation can be applied to a wide range of unsaturated compounds and is hence suitable for the synthesis of fine chemicals.

Conjugated dienes can be hydroformylated with rhodium carbonyl phosphine catalysts to give dialdehydes. The same catalyst allows allyl alcohols to be hydroformylated without isomerization. Unsaturated carboxylic acids and their esters are also suitable starting materials for rhodium- or cobalt-catalyzed oxo synthesis.

A further important group of CO reactions is the reaction of carbon monoxide with functionalized compounds such as alcohols, esters, and nitro and halogeno compounds. An industrially important reaction is the Monsanto acetic acid process (→ Acetic acid, Chap. 4.1.), which involves the carbonylation of methanol with an iodine-modified rhodium catalyst. The methanol is converted to methyl iodide, which oxidatively adds to the rhodium complex. After formation of an acyl complex, acetyl iodide is eliminated and then reacts with water to give acetic acid. The Monsanto process can be carried out under mild conditions (175 °C, 5 MPa) and gives high yields of acetic acid (90 %) with excellent selectivity (>99 %).

Homologation is another process in which methanol is converted to C_2 species by reaction with synthesis gas. Use of cobalt – iodine catalysts gives high yields of acetaldehyde. The addition of ruthenium increases the hydrogenation activity of the catalysts and leads to preferential formation of ethanol.

In the acetic anhydride process, jointly developed by Tennessee Eastman and Halcon SD, methyl acetate is carbonylated in the presence of rhodium – iodine catalysts (→ Acetic Anhydride and Mixed Fatty Acid Anhydrides, Chap. 1.3.3.). As in the Monsanto process, the catalytically active species appears to be the complex $[RhI_2(CO)_2]^-$. The process is noteworthy in that it for the first time allowed the production of acetic anhydride from coal-based synthesis gas, independent of petrochemical feedstocks.

$$CO + 2H_2 \longrightarrow CH_3OH \xrightarrow{CH_3COOH} CH_3COOCH_3 \xrightarrow{CO} (CH_3CO)_2O$$

Benzyl bromide undergoes a double carbonylation in the presence of cobalt catalysts and lithium hydroxide to give phenyl pyruvic acid [*156-06-9*]. The palladium-catalyzed reaction of carbon monoxide with aromatic nitro compounds affords industrially important isocyanates.

Finally, some processes are listed that are either under development or are aldready used to a limited extent industrially (see figure above). Noteworthy are the Ube oxalic acid synthesis by oxidative coupling of carbon monoxide (→ Oxalic Acid); the Enichem dimethylcarbonate process involving oxidative carbonylation of methanol; the Asahi carbamate synthesis; the homologation of acetic acid to give propionic acid (Texaco); and the Halcon process for the synthesis of vinyl acetate from methyl acetate and synthesis gas.

3.2.8. Functionalization [469–505]

Functionalization is the addition of a molecule of type HY or YX_2 to C–C multiple bonds. The former reaction type includes hydroboration, hydroalumination, hydrocyanation, hydrosilylation, and hydroamination, while the latter includes cyclopropanation (see Section 3.2.4) and carboxylation with CO_2. Hydroboration ($HY=HBX_2$) normally occurs without catalysis. In some cases, however, titanium salts or complexes have proved to be effective catalysts. For example, the hydroboration of 1-octene with lithium borohydride is catalyzed by titanocene dichloride. Work up with sodium methoxide and hydrogen peroxide gives the 1- and 2-octanols in almost 100 % yield.

$$R{-}CH{=}CH_2 \xrightarrow[{[TiCp_2Cl_2]}]{LiBH_4} Li\left[(RCH_2CH_2)_nBH_{4-n}\right]$$

$$\xrightarrow[H_2O_2]{CH_3ONa} R{-}CH_2{-}CH_2{-}OH$$

The low solubility of $NaBH_4$ in organic solvents can be overcome by use of phase-transfer catalysts such as 18-crown-6. The system $TiCl_3/NaBH_4$/18-crown-6 allows many hydroborations to be carried out at room temperature. Dienes with isolated double bonds can be selectively hydroborated at one double bond. Thus, 1,7-octadiene [*3710-30-3*] can be converted to 8-hydroxy-1-octene [*13175-44-5*] in 80 % yield. Hydroalumination ($HY = HAlX_2$) of olefins is an important method for synthesizing organoaluminum compounds. Important catalysts are $TiCl_4$, $TiCl_3$, $TiCp_2Cl_2$, and $Ti(OR)_4$; zirconium

compounds ($ZrCl_4$, $ZrCp_2Cl_2$) and nickel phosphine complexes can also be used. The most reactive substrates are terminal olefins, and the reactivity of the aluminum hydrides decreases in the order:

$$AlH_3 > H_2Al-Cl > [(R_3Si)_2N]_2Al-H > (R_2N)_2Al-H > HAlCl_2$$

An advantage of hydroalumination over hydroboration is that oxidation of the Al – C bond does not require peroxide, but can be carried out with oxygen. However, attack occurs at functional groups other than the double bond.

Catalytic hydrocyanation (HY = HCN) is a good method for the synthesis of alkyl nitriles and dinitriles, which are starting materials for amides, amines, and carboxylic acids. Although the most important catalysts are nickel complexes, complexes of cobalt, palladium, and copper are also active. An example of the hydrocyanation of a terminal olefin is the addition of HCN to 1-octene. With the catalyst $[Ni\{P(OPh)_3\}_4]$ and cocatalyst $AlEtCl_2$, the anti-markovnikov adduct, 1-nonanenitrile, is obtained with 80 % selectivity.

Octenes with internal double bonds give 1-nonanenitrile with the same selectivity, suggesting that a nickel-catalyzed isomerization of the double bond occurs before addition. The mechanism of hydrocyanation involves a hydrido cyano species, which reacts with the olefin to give an alkylcyano intermediate. After elimination of the nitrile, the hydrido cyano species is reformed by addition of HCN.

Stereoselective hydrocyanation can be carried out by using catalysts with chiral ligands. The complex $[Pd(DIOP)_2]$ leads exclusively to formation of threo isomers.

Hydrocyanation can also be carried out with substituted olefins such as styrene or acrylonitrile and cyclic olefins such as cyclopentene or norbornene. Of particular industrial interest is the double hydrocyanation of butadiene to form adiponitrile, which is hydrogenated to hexamethylenediamine, an important precursor for nylon 66. The hydrocyanation of butadiene has been carried out by DuPont since 1971 with nickel(0) phosphite complexes as catalysts.

The reaction occurs stepwise, involving hydrocyanation to give 3-pentenenitrile, isomerization to form 4-pentenenitrile, and a further hydrocyanation step in which adiponitrile is formed. The mechanism is believed to involve an allyl nickel complex as the reactive intermediate. Because addition of the cyano group to the 4-carbon atom is strongly favored, the first hydrocyanation step gives pentenenitrile and not the isomeric methyl branched product.

Hydrosilylation (HY = $HSiR_3$) of olefins leads to a range of functionalized silanes that are valuable starting materials in organic synthesis. The most important catalytic metals are platinum, rhodium, and nickel, but reactions with vanadium, palladium, ruthenium, iron, and

cobalt catalysts have also been reported. The reactivity of the silanes decreases in the order:

$$HSiCl_3 > HSiCl_2Et > HSiClEt_2 > HSiEt_3 > HSiPr_3$$

That is, the reactivity decreases with increasing electron density on the silane hydrogen atom. These electronic effects are, however, strongly influenced by additional steric effects.

The reactivity also varies between terminal and inner alkenes. For example, the rhodium-catalyzed hydrosilylation of 1-heptene with trichlorosilane proceeds in 54 % yield, whereas the analogous reactions with *cis*- and *trans*-2-heptene give yields of only 10 % and 1 %, respectively. Therefore, dienes that have double bonds of differing reactivity can often be selectively monosilylated. For example, in the presence of nickel or platinum catalysts, 4-vinylcyclohexene reacts only at the exocyclic double bond. Conjugated dienes such as butadiene can also be hydrosilylated. The proportions of the 1,2 and 1,4 addition products and the *cis/trans* ratio of the product depends on the catalyst and silane used. Hydroamination ($HY = HNR_2$) of mono- and dialkenes with primary or secondary amines leads to the corresponding higher substituted amines. Important catalysts are salts or complexes of palladium, rhodium, nickel, platinum, and iridium. An example is the reaction between 1-butene and dimethylamine, which affords a mixture of two isomeric butyl dimethyl amines.

$$CH_3-CH_2-CH=CH_2 + HNMe_2 \xrightarrow{[Pd]} C_4H_9-NMe_2 + C_2H_5-CH(CH_3)-NMe_2$$

A special functionalization reaction is the carboxylation of unsaturated compounds with carbon dioxide. The reaction of alkynes with CO_2 in the presence of nickel catalysts gives doubly substituted pyrones. The mechanism involves an oxanickelcyclopentene complex, which undergoes ring enlargement by insertion of an alkyne to give a 7-membered ring. Decomposition of the 7-membered ring liberates the pyrone and reforms the nickel catalyst.

Methylene cyclopropanes can be converted to γ-lactones by palladium catalysis, while allene gives esters.

The reaction between butadiene and carbon dioxide can be controlled to give δ- or γ-lactones by judicious choice of the catalyst and reaction conditions. Two butadiene molecules couple at the palladium center to give a bis(η^3-allyl) complex. Carbon dioxide then inserts in one allyl bond, giving an allylcarboxylate complex from which the lactone can be liberated (see figure below).

Mixtures of dienes (e.e., butadiene and isoprene) also react with CO_2 in the presence of palladium catalysts.

3.2.9. Alkane Activation [506–531]

In theory, it should be possible to carry out alkane activation – the functionalization of unsaturated hydrocarbons – in homogeneously catalyzed reactions.

The hydrido alkyl intermediate is, however, highly unstable and generally undergoes spontaneous reductive elimination of the alkane. Nevertheless, it has been shown in stoichiometric reactions that alkane activation is possible. Some examples include:

Future research in this area will show whether catalytic alkane activation can achieve practical importance.

1. Introduction

Oxalic acid, ethanedioic acid, acidum oxalicum, has the structural formula

and is the simplest saturated dicarboxylic acid [1]. The compound exists in anhydrous form [*144-62-7*] or as a dihydrate [*6153-56-6*]. The anhydrous acid is not found in nature and must be prepared from the dihydrate even when produced industrially. Oxalic acid is widely distributed in the plant and animal kingdom (nearly always in the form of its salts) and has various industrial applications.

The acidic potassium salt of oxalic acid is found in common sorrel (Latin: oxalis acetosella) and the name oxalic acid is derived from that plant. Examples of plants in which oxalic acid occurs (in the form of potassium, sodium, calcium, magnesium salts, or iron complex salts) are given below (oxalic acid content in milligrams per 100 g dry weight):

Spinach	460 – 3200
Rhubarb	500 – 2400
Chard	690
Parsley	190
Beets	340
Cocoa	4500
Tea	3700
Beet leaves	up to 12 000

Oxalic acid is formed in plants through incomplete oxidation of carbohydrates, e.g., by fungi (*Aspergillus niger*) or bacteria (*acetobacter*) and in the animal kingdom through carbohydrate metabolism via the tricarboxylic acid cycle. The urine of humans and of most mammals also contains a small amount of calcium oxalate. In pathological cases, an increased calcium oxalate content in urine leads to the formation of kidney stones [2]. Calcium and iron(II) oxalates are also found as minerals.

Oxalic acid is one of the oldest known acids and was already identified in the potassium salt of sorrel by WIEGLEB in 1769. The compound also has historical significance in chemistry because WOEHLER prepared oxalic acid by hydrolysis of cyanogen [*460-19-5*] in 1824, thereby synthesizing the first natural product, even before his famous urea synthesis in 1828.

2. Physical Properties

Both the anhydrous and dihydrated forms of oxalic acid form colorless and odorless crystals.

2.1. Anhydrous Oxalic Acid

Anhydrous oxalic acid [*144-62-7*] exists as rhombic crystals in the α-form and as monoclinic crystals in the β-form [3]. These forms differ mainly in their melting points. The slightly stable β-form changes into the α-form at 97 °C and 0.2 bar. Anhydrous oxalic acid is prepared by dehydration of the dihydrate through careful heating to 100 °C. It is then sublimated in a dry air stream. The sublimation is fast at 125 °C and can be carried out at temperatures up to 157 °C without decomposition. The dehydration can also be accomplished by azeotropic distillation with benzene or toluene [4]. Anhydrous oxalic acid is slightly hygroscopic, it absorbs water from moist air ("weathers") to form the dihydrate again. The hydration occurs very slowly because of surface caking. The physical and thermal chemical properties of anhydrous oxalic acid may be summarized as follows:

M_r	90.04
mp	
α	189.5 °C
β	182 °C
Decomposition temperature	187 °C
Density d_4^{20}	
α	1.900 g/cm^3
β	1.895 g/cm^3
Refractive index β, n_4^{20}	1.540
Vapor pressure (solid, 57 – 107 °C)	$\log P = -(4726.95/T) + 11.3478$ kPa
Specific heat (solid, −200 to 50 °C)	$c_p = 1.084 + 0.0318\,t$ J/g
Heat of combustion ΔH_c° (25 °C)	−245.61 kJ/mol
Standard enthalpy of formation $\Delta H^\circ{}_f$ (25 °C)	−826.78 kJ/mol
Standard free energy of formation $\Delta G^\circ{}_f$ (25 °C)	−697.91 kJ/mol
Heat of solution (in water)	−9.58 kJ/mol
Heat of sublimation	90.58 kJ/mol
Heat of decomposition	826.78 kJ/mol
Entropy, S° (25 °C)	120.08 J mol^{-1} K^{-1}
Thermal conductivity (0 °C)	0.9 W m^{-1} K^{-1}
Ionization constant	
K_1	6.5×10^{-2}
K_2	6.0×10^{-5}

2.2. Oxalic Acid Dihydrate

Oxalic acid dihydrate [*6153-56-6*], HOOC−COOH · 2 H_2O is the industrially produced and usual commercial form of oxalic acid. The compound forms colorless and odorless prisms or granules that contain 71.42 wt % oxalic acid and 28.58 wt % water. Oxalic acid dihydrate is stable at room temperature and under normal storage conditions. The most important physical properties are as follows:

M_r	126.07
mp	101.5 °C
Density d_4^{20}	1.653 g/cm^3
Refractive index n_4^{20}	1.475
Standard enthalpy of formation ΔH_f° (18 °C)	−1422 kJ/mol
Enthalpy of solution (in water)	−35.5 kJ/mol
pH (0.1 M solution)	1.3
Water vapor partial pressure	
at 20 °C	2.5 kPa
at 50 °C	20 kPa
Bulk density, regular product	0.977 g/cm^3
Bulk density, coarse product	0.881 g/cm^3

The solubility in water and the density of these solutions are presented in Table 1 [5]. Oxalic acid is readily soluble in polar solvents such as alcohols (although partial esterification occurs), acetone, dioxane, tetrahydrofuran, and furfural. Oxalic acid is sparingly soluble in diethyl ether (1.5 g oxalic acid dihydrate in 100 g ether at 25 °C), and insoluble in benzene, chloroform, and petroleum ether. The ionization constants show that oxalic acid is a strong acid. The value of K_1 is comparable to that of mineral acids and the value of K_2 corresponds to ionization constants of strong organic acids, for example, benzoic acid.

Table 1. Solubility of oxalic acid in water at different temperatures and corresponding densities

3. Chemical Properties

In the homologous series of dicarboxylic acids, oxalic acid, the first member, shows unique be-

havior because of the interaction of the neighboring carboxylate groups. This results in an increase in the value of the dissociation constant and in the ease of decarboxylation: Upon rapid heating to 100 °C oxalic acid decomposes into carbon monoxide, carbon dioxide, and water with formic acid as an isolable intermediate. In aqueous solution decomposition is induced by light, and to a much greater extent by γ- or X-rays (to carbon monoxide, carbon dioxide, formic acid, and occasionally hydrogen). This decomposition is catalyzed by the salts of heavy metals, for example, by uranyl salts. Oxalic acid cannot form an intramolecular anhydride. Upon heating to over 190 °C or warming in concentrated sulfuric or phosphoric acid, oxalic acid decomposes to carbon monoxide, carbon dioxide, and water: this decomposition is not exothermic.

Ease of reaction with oxygen is also a typical characteristic of oxalic acid:

$$HOOC{-}COOH + 1/2\ O_2 \longrightarrow 2\ CO_2 + H_2O$$

This reaction can be exploited in quantitative analysis (Manganometry, see Chap. 5).

The reducing properties of oxalic acid (which itself is oxidized to the harmless end products carbon dioxide and water) form the basis for the variety of practical applications (see Chap. 6). Oxalic acid is also oxidized relatively easily to carbon dioxide by many other oxidizing agents in addition to air, especially in the presence of the salts of heavy metals. Oxalic acid is easily esterified, whereby two types, the acidic mono or neutral diesters can result. These esters are applied as intermediates in chemical syntheses. They react relatively easily with water, ammonia, or amines to afford the corresponding acyl derivatives.

Important chemical characteristics are also demonstrated by the metal salts of oxalic acid. These exist in two types–the acidic and neutral salts. The alkali metal and iron (III) salts are readily soluble in water. All other salts are sparingly soluble in water. The near complete insolubility of the alkaline-earth salts of oxalic acid, especially of calcium oxalate, finds some applications in quantitative analysis. When heated all these metal salts lose carbon monoxide. Other salts which are easier decomposable lose carbon dioxide in addition. The alkali and alkaline-earth salts form carbonates under these conditions. Manganese, zinc, and tin salts form oxides; iron, cadmium, mercury, and copper salts form mixtures of oxides and metals. Nickel, cobalt, and silver salts afford pure metals. Anhydrous fusion of oxalates with alkali yield carbonates and hydrogen. For review see [6].

4. Production Processes and Raw Materials

There are many industrial processes for the production of oxalic acid, which have been carried out by a large number of companies and are in part still used today. In recent years both the number of firms producing oxalic acid and the number of starting materials used for its production have been reduced. Generally, only three classes of compounds are employed as raw materials for the production of oxalic acid. These are:

carbohydrates (including ethylene glycol and molasses)
olefins
carbon monoxide

Nevertheless, three outdated methods, which have been abandoned in important industrial nations for economic reasons, are described briefly [7], because in the third world small firms might exist that still employ these production methods:

1) The sodium formate method, which is also based on carbon monoxide as the raw material, but involves very cumbersome procedures of questionable technical safety that are no longer economically feasible (heating to 400 °C, elimination of hydrogen, calcium precipitation, and precipitation with sulfuric acid). Nevertheless, this process is probably still being used in China.
2) The alkali fusion of cellulose, which is the oldest production method [8]. Although cellulose-containing material from every source can be used in this method, this process has been discontinued because of the low yields, large amounts of required alkali and sulfuric acid, and the large amounts of wastewater.
3) The isolation of oxalic acid as a byproduct of carbohydrate fermentation, for example, in the synthesis of citric acid [9]. The process involves the biotechnical exploitation

of the tricarboxylic acid cycle through enzymatic cleavage of sugars. The intermediary formed oxalacetic acid esters and oxalosuccinic acid (1-oxopropane-1,2,3-tricarboxylic acid) esters are cleaved by hydrolases. Especially because of the handling of large amounts of water, this process is no longer economically feasible.

In all industrial processes, oxalic acid is produced as the crystalline dihydrate. In the following sections four methods are described that are currently used industrially. Three of them are based on a nitric acid oxidation and one is a synthesis using carbon monoxide. A new review of oxalic acid production from various sources is given in [10].

4.1. Oxidation of Carbohydrates

This method, the oldest of chemical productions, was in principal discovered by SCHEELE more than 200 years ago (1776). He oxidized sugar with concentrated nitric acid to oxalic acid. However, it was not until ca. 1940 that this process gained industrial importance when the nitrogen oxides produced in the reaction could be recovered and recycled. In Germany, I.G. Farben produced 2000 t of oxalic acid per year by this method until 1944 [11]. This process is employed in Brazil, China, and in several Eastern European countries. Raw materials employed in this process include sugar, glucose, fructose, corn starch, wheat starch, reclaimed starch, potato starch, corncobs, tapioca, and molasses. Choice of starting material depends on availability and price and on optimization of the reaction process involved. For example, depending on the starting materials foam, greases, slime, and varying yields can be expected and must be dealt with accordingly [1]. Molasses and other agricultural waste have gained increasing importance as raw materials. These materials are not only inexpensive, but must be further processed in any case due to environmental reasons. Molasses contains, as a production residue of sugar refinement, many nitrogen-containing compounds, which are, however, for the most part removed during the nitric acid oxidation. This explains the difficulties encountered with excessive foam formation during production that must be overcome. If starch products are used as raw materials they must be hydrolyzed to glucose in an extra batchwise step prior to the actual oxidation [12, 13]. This is carried out by boiling the starch suspension in the presence of oxalic acid or sulfuric acid for about six hours. The oxidation of the resulting glucose and the following steps are then essentially continuous operations. The oxidation occurs according to the following idealized equation:

$$C_6H_{12}O_6 + 6\,HNO_3 \xrightarrow{V_2O_5,\ Fe^{3+}} 3\,(COOH)_2 + 6\,NO + 6\,H_2O$$

In fact besides NO other nitrogen oxides such as NO_2, N_2O, N_2O_5 are formed.

Allied Chemical Process. The Allied Chemical process is schematically presented in Figure 1. The concentration of the glucose solution obtained by hydrolysis of starch is approximately 50 – 60 wt %. This material, along with the recycled supernatent from the crude centrifugation, is placed in a reactor with ca. 50 % sulfuric acid, vanadium pentoxide (0.001 – 0.05 wt %) and iron (III) sulfate (0.39 – 0.8 wt %), based on the total mass of the mixture. Nitric acid (65 %) is then added slowly under vigorous stirring in a tightly controlled temperature range around 70 °C– the temperature range differs according to the raw material being used. The strongly exothermic reaction must be well cooled. Air is simultaneously blown into the reactor to support the reaction and to remove NO and other nitrogen oxides of low oxidation number. The nitrogen oxides expelled are collected in an adsorption system and are recycled after oxidation. Crude oxalic acid is obtained after cooling and centrifugation of the reaction mixture. The crude acid is again dissolved in hot water, put through a grease separator and recrystallized. After a second centrifugation and drying, oxalic acid dihydrate is obtained with a purity >99 %. Precise control of the reaction parameters is critical for a good yield [14]. For good quality raw materials ca. 65 % of the theoretical yield is obtained. The absent ca. 35 % of the yield mainly results from losses through CO_2 formation. This process is employed today in Spain, Brazil, The People's Republic of China, Taiwan, Korea, and India.

Figure 1. Production of oxalic acid by oxidation of carbohydrates (Allied Chemical process)

4.2. Oxidation of Ethylene Glycol

The oxidation of ethylene glycol with nitric acid is a one-step process. A flow chart is shown in Figure 2. An oxidizing mixture of 30 – 40 % sulfuric acid and 20 – 25 % nitric acid is used. The oxidation is carried out in the presence of vanadium pentoxide and iron (III) salts, at 50 – 70 °C and atmospheric pressure. Only CO_2 is formed as a byproduct. This original process has been improved by the Mitsubishi Gas Company and in Japan most of the oxalic acid is produced this way [15]. The improved process operates at about 10 bar in a pressure reactor, in which ca. 60 % nitric acid and possibly also sulfuric acid at 80 °C, is pressurized with oxygen at 3 – 10 bar. Ethylene glycol is then continually pumped in and the temperature and pressure are maintained by addition of oxygen. The exothermic reaction must be held at a temperature of 50 – 70 °C by effective cooling. The yield of oxalic acid, based on ethylene glycol, is 90 – 94 % of the theoretical value. The nitric acid used can be recovered almost completely. This indicates that the nitrogen oxides and nitric acid only act as catalysts and the actual oxidation has been effected by oxygen. The idealized overall equation for this reaction is:

$$\begin{array}{c}CH_2OH\\|\\CH_2OH\end{array} + 2O_2 \xrightarrow[V_2O_5,\ Fe^{3+}]{NO_2} \begin{array}{c}COOH\\|\\COOH\end{array} + 2H_2O$$

Figure 2. Production of oxalic acid from ethylene glycol

Other suitable starting materials are propylene glycol, acetaldehyde, or glycolic acid. Vanadium compounds (0.001 – 0.1 wt %) are recommended as promoters. Sodium nitrite, formic acid, or formaldehyde are recommended as initiators [16]. Ube Industries in Japan have further developed the process so that it operates only with nitric acid (no sulfuric acid), however, pressure is required. In an oxalic acid process developed in the former Soviet Union a mixture of nitric and sulfuric acids is used. The reaction is performed at 1.3 – 4.0 kPa (the pressure is less than that employed in the Mitsubishi process) to remove NO_x more effectively.

Although the ethylene glycol process clearly affords the best yields by a wide margin, the corn starch and molasses oxidations are still more advantageous from an economic point of view. Ethylene glycol oxidation is carried out only by Mitsubishi in Japan.

4.3. Oxidation of Propene

The second most important industrial process for the production of oxalic acid (after carbohydrate oxidation) is the reaction of propene with nitric acid. The worldwide production of oxalic acid by this method in 1978 was 65 000 t/a. Pure propene or propene rich fractions from petrochemical refineries can be used as feedstocks. This earlier developed reaction was significantly improved by Rhône-Poulenc in France by technical engineering and construction improvements and strict observance of the reaction conditions. These refinements increased the yield and solved the serious safety problems [17]. Rhône-Poulenc is reputed to be the largest oxalic acid producer in the world. The two-step process can be represented by the following equations approximate stoichiometry:

Initial stage:

$$\underset{\text{Propene}}{CH_3CH{=}CH_2} + 3\,HNO_3 \longrightarrow \underset{\alpha\text{-Nitratolactic acid}}{CH_3\underset{\underset{ONO_2}{|}}{C}HCOOH} + 2\,NO + 2\,H_2O$$

Final stage:

$$CH_3\underset{\underset{ONO_2}{|}}{C}HCOOH + 5/2\,O_2 \longrightarrow \underset{\text{Oxalic acid}}{HOOC-COOH} + CO_2 + HNO_3 + H_2O$$

Figure 3. Production of oxalic acid from propene

Process Description (see Fig. 3). Propene is introduced into a solution of nitric acid (50 – 75 wt %) in the first reactor at 10 – 40 °C, while keeping the molar ratio of propene to nitric acid at 0.01/1.0 – 0.5/1.0 to produce watersoluble intermediates of α-nitratolactic acid and lactic acid. In the second step the solution of these partially oxidized products is treated with oxygen at 45 – 100 °C in the presence of a catalyst. Oxalic acid is formed, crystallized, and filtered. The overall yield based on propene is claimed to be ca. 90 % and the conversion of propene is ca. 100 %. The nitrogen oxides are removed from the second reactor and recovered. The consumption of nitric acid is 1.2 kg per kg of oxalic acid dihydrate produced. The process can also be employed for the production of lactic acid instead of oxalic acid. An improvement in the yield is achieved by addition of catalysts (salts or compounds containing Fe, Al, Cr, Sn, Bi, or I). In the chemical industry chromium (III) nitrate, iron (III) nitrate or tin (II) chloride are employed in quantities of 0.4 – 0.5 wt % (based on the metal) and dissolved in 65 % nitric acid. The scope and limitations of this process are restricted by safety

problems because the nitrates of α-hydroxycarboxylic acids that are formed as intermediates from α-olefins and NO_2 are unstable and lead to uncontrollable decomposition and violent explosions [18]. As a result many technical difficulties need to be overcome to carry out these processes. Today this process is only operated by Rhône-Poulenc. Analogous to propene, ethylene can also be oxidized to oxalic acid.

4.4. Production from Carbon Monoxide [19,20]

The newest process for the industrial production of oxalic acid was developed by Ube Industries. Their synthesis is performed in two steps. In the first step CO and a lower alcohol are reacted under pressure and in the presence of a catalyst to form the corresponding diester of oxalic acid. This diester is hydrolyzed in the second step to oxalic acid and the original alcohol which is then recycled. Palladium on charcoal and alkyl nitrites are employed as catalysts and the reaction is carried out at 10 – 11 MPa. *n*-Butanol is the preferred alcohol and is simultaneously used as the solvent. This process has the advantage of inexpensive starting materials, however, it is disadvantageous with regard to the much higher capital investment (high pressure) and utility costs.

$$2\,CO + 2\,ROH + 1/2\,O_2 \xrightarrow{\text{Pd/C, RONO}} \begin{matrix}COOR\\ |\\ COOR\end{matrix} + H_2O \quad (1)$$

$\Delta H = -52.8$ kJ/mol

Oxalic acid

$$\begin{matrix}COOR\\ |\\ COOR\end{matrix} + 2\,H_2O \longrightarrow \begin{matrix}COOH\\ |\\ COOH\end{matrix} + 2\,ROH \quad (2)$$

New perspectives and developments are given in [21]. The use of palladium catalysts is discussed in [22].

The catalytic action of the alkyl nitrite on the first reaction is believed to be the following:

$$2\,RONO + 2\,CO \longrightarrow (COOR)_2 + 2\,NO \quad (3)$$

$$2\,NO + 1/2\,O_2 + 2\,ROH \longrightarrow RONO + H_2O \quad (4)$$

Butyl nitrite and methyl nitrite are the preferred alkyl nitrites for industrial purposes. The first plant using butyl nitrite in the production of oxalic acid was constructed in 1978 (6000 t/a oxalic acid). The advantages of using butyl nitrite are as follows:

1) It functions not only as reaction component but also as a dehydrating agent. Butyl nitrite has a higher boiling point than water and butyl nitrite and water form an azeotropic mixture with a lower boiling point than butyl nitrite. Thus, the water formed can be removed as an azeotropic mixture and most of the butyl nitrite remains in the system. Butyl nitrite is recovered from the azeotropic mixture and reused.
2) Butyl nitrite is finally hydrolyzed to butanol which can easily be separated from oxalic acid solution by phase separation.

A flow chart of the process using butyl nitrite is given in Figure 4. A circulation liquid containing butyl nitrite, butanol, and the palladium catalyst and a circulation gas containing carbon monoxide and oxygen are pressurized and fed to a reaction tower. Here dibutyl oxalate is formed and butyl nitrite is consumed (Eq. 3). Butyl nitrite is regenerated simultaneously (Eq. 4). Both reactions are exothermic. The selectivity for dibutyl oxalate increases with increasing reaction pressure and decreasing reaction temperature; however, the velocity of the reaction increases with increasing temperature. Thus, the reaction is conducted industrially at 10 – 11 MPa and 90 – 100 °C.

Gas circulation is carried out in order to hold the oxygen concentration below the explosion limit during the reaction and to improve the carbon monoxide utilization and gas–liquid contact rate.

The solution released from the tower is flashed to evaporate the carbon dioxide gas formed as a byproduct. The reaction water is removed by azeotropic distillation with butyl nitrite and most of the solution is recycled to the reaction tower. Part of the solution is further processed: it is first filtered to separate the catalysts; then butyl nitrite, and butanol are removed to yield pure dibutyl oxalate. The palladium catalyst, butyl nitrite, and butanol are recovered and returned to the circulation liquid, which is also supplied with make-up butanol and nitric acid. The circulation liquid is then pressurized and fed back to the reaction tower.

Figure 4. Production of oxalic acid from carbon monoxide an butanol using butyl nitrite as catalyst

The refined dibutyl oxalate is mixed with the mother liquor from the oxalic acid crystallization and hydrolyzed at about 80 °C into oxalic acid and butanol. The oxalic acid solution and butanol are separated by phase separation. Then oxalic acid dihydrate is crystallized from the oxalic acid solution, and butanol is recycled to the process after refining. A gas-phase process using methyl nitrite has been established [21, 22]. This process employs a lower reaction pressure (390 kPa) and is more economic than the liquid-phase method because of the following reasons:

1) The consumption of electric power is greatly reduced owing to the low pressure operation (about 60 % saving).
2) Dimethyl oxalate formation and methyl nitrite regeneration reaction are separated; hence, side-reactions are decreased and the yield of dimethyl oxalate is increased (98 %).
3) Inexpensive methanol is used instead of butanol.

4.5. Production of Anhydrous Oxalic Acid

In all processes oxalic acid is obtained as the dihydrate. Anhydrous oxalic acid can be obtained by heating oxalic acid dihydrate to ca. 3 °C below its melting point or by azeotropic distillation with benzene or toluene. The demand for anhydrous oxalic acid is, however, very low.

5. Chemical Analysis

Qualitative Analysis. Upon heating oxalic acid with diphenylamine a blue color results, the so-called "aniline blue". Analysis limit: 5 µg [23].

Quantitative Analysis. In addition to simple acid–base titration, which of course can only be conducted in the absence of other acids, four important analytical methods exist.

Manganometry. As the reaction of oxalic acid and $KMnO_4$ is quantitative, oxalic acid can be easily titrated with a standard solution of $KMnO_4$.

$$5\,(COOH)_2 + 2\,KMnO_4 + 3\,H_2SO_4 \longrightarrow K_2SO_4 + 2\,MnSO_4 + 10\,CO_2 + 8\,H_2O$$

This method can only be used in the absence of other reducing agents.

Gravimetry. Because of the insolubility of calcium oxalate in water (100 g of water at 18 °C dissolves only 0.0006 g of calcium oxalate), oxalic acid can be very easily and quantitatively precipitated out of aqueous solutions, e.g., with calcium chloride. The oxalic acid content of the precipitate is determined either gravimetrically (after ashing as CaO) or manganometrically.

Determination by HPLC. In this determination the oxalic acid must be esterified, separated by HPLC and analyzed by gas chromatography subsequently [24].

Enzymatic Determination. This method is usually used for analysis of oxalic acid in biological material, such as in fruit or vegetables and in body fluids. Either oxalate oxidase [25, 26], oxalate decarboxylase, or formate dehydrogenase are employed [27].

6. Uses

Apart from the application of oxalic acid as a synthetic intermediate, the properties of oxalic acid or its salts have generally been exploited as reducing agents (in which case the harmless final products of carbon dioxide and water are formed), as precipitants for calcium ions, or as complexing agents for the salts of heavy metals. The principal applications worldwide can be divided into the following groups in percentages of total use:

Metal treatment	ca. 28 %
Textile treatment	ca. 25 %
Bleaching agents	ca. 20 %
Chemical uses	ca. 27 %

6.1. Metal Treatment

Sodium, potassium, or ammonium oxalates form soluble double salts with heavy metals, especially iron. Iron (III) oxalate is the only readily soluble heavy metal salt. Oxalic acid salts are therefore used (1) for rust removal, e.g., from cooling systems (automobile radiators), boilers, or from steel plates before phosphating, (2) for removal of iron veins in marble, (3) as a constituent of metal cleaners with rust protection, especially for use on copper, silver, or aluminum, (4) in anodizing of aluminum, for the formation of very hard, abrasion and corrosion protective coatings, where through the use of additives different surface colors can be imparted to aluminum [28, 29]. Oxalic acid is also used for the cleaning of materials for electronic devices, and as coatings for protection of stainless steel, nickel alloys, chromium, alloy steels, and titanium [30, 31].

6.2. Textile Treatment

Oxalic acid is used as mordant for the printing and dyeing of wool and cotton. It serves as a stripping agent for wool colors for special pattern affects, as auxiliary in indigo caustic discharge printing, and is used in vat dyeing as a reducing agent for potassium dichromate. In laundries oxalic acid is used for the removal of rust stains and the neutralization of alkalinity. It also has an antibacterial effect [32]. Oxalic acid can be employed as a catalyst for cross linking of textile finishing agents in the permanent pressing of cellulose fabrics and for flameproofing [33].

6.3. Bleaching Agents

Oxalic acid is used in the tanning and bleaching of leather, and in bleaching of cork, wood (especially veneered wood), straw, cane, feathers as well as natural and synthetic waxes. The majority of oxalic acid is used for the bleaching of pulpwood. In leather processing oxalic acid is used in whitening instead of sodium dithionite.

6.4. Chemical Uses

Preparation of Esters and Salts. Because of the two carboxyl groups oxalic acid forms acid esters and salts as well as normal esters and salts.

Reagent in Chemical Synthesis. Since oxalic acid is a strong dehydrating agent it can be used in condensation reactions, in the esterification of secondary alcohols to esters, or in cyclization reactions [34].

Oxalic acid	$1.10/kg
Ammonium oxalate	$3.80/kg
Ammonium iron (III) oxalate	$4.40/kg
Potassium oxalate	$4.60/kg
Sodium oxalate	$5.50/kg

Concentration of Rare Earth Elements. Oxalic acid is used for the concentration and isolation of rare earth elements from aqueous solutions that are formed during the digestion of lanthanide ores (for example, monazite) with sulfuric, hydrochloric, or phosphoric acids. The

precipitation of oxalates is almost quantitative even from strongly acidic solutions. After precipitation the oxalates are converted to their oxides by heating and processes further in this form [35,36].

Other Uses. Small particles or powders, which are prepared from oxalates, are used for magnetic recording tapes. Oxalic acid is used for the preparation of polyester oxalates and copolyoxamides [37,38]; for the production of inks, pigments, and paints [39]; and for the preparation of catalysts especially those which contain precious metals and as redox initiators.

7. Economic Aspects

Specification for commercial-grade oxalic acid dihydrate is a purity of >99.5 %. Supply and demand in the world market is presented in Table 2. No significant increase in demand is anticipated since no new application areas are indicated. The average prices per kilogram in the United States (truckload quantities) in 1988 were [40]:

The most important producers of oxalic acid are:

Western Europe:	Rhône-Poulenc (Chalampé, France)
	Soc. Franc. Hoechst (Trosly–Breuil, France)
	EniChem Sintesi (Pieve-Vergonte, Spain)
	DAVSA (Vimbodi, Spain)
Japan:	Mitsubishi Gas (Yokkaichi, Mie)
	Ube Industries (Ube, Yamaguchi)
Taiwan:	Uranus Chemicals (Hsinchu, Hsien)

8. Storage, Handling, Transportation, Waste Disposal

Dry oxalic acid is packed and sold in polyethylene lined multilayered bags or in polyethylene or poly(vinyl chloride) vessels or drums. Reinforced fiberglass plastics are also used commonly and are recommended for storage.

Oxalic acid is not flammable and also not self inflammatory up to 400 °C. It is not shock sensitive and does not cause dust explosions. Oxalic acid is a weakly dangerous substance for water (hazard class 1) and exhibits low toxicity for fish and bacteria. Labelling according to Gef Stoff V: X_n (less poisonous). R-phrase: 21/22 (dangerous to health through contact with the skin and through ingestion); S-phrase: 2, 24/25. For inhalation protection masks with fine particle filters (filter class P 2) and protective gloves made from PVC or rubber are recommended [41].

∗ Data are from an Ube survey, 1. Feb. 1990; data are given in 1000 t.

Neither oxalic acid nor its solutions should be discarded in the environment before proper treatment. Common treatments include incineration or heating with sulfuric acid to convert it to carbon monoxide, carbon dioxide, and water. Small amounts of oxalic acid can be treated with potassium permanganate to give carbon dioxide. Neutralization with lime results in precipitation of insoluble calcium oxalate. The latter can be safely deposited.

9. Derivatives

9.1. Salts

In addition to neutral and acid salts, oxalic acid also forms many complex compounds that easily crystallize. Simple oxalates of nearly all organic and inorganic bases are known. The three most important salts of oxalic acid are potassium hydrogen oxalate (salt of sorrel), ammonium oxalate, and ammonium iron (III) oxalate. All other salts of oxalic acid are less important industrially.

Potassium oxalate [*583-52-8*], $K_2C_2O_4 \cdot H_2O$, M_r 184.24, has the highest water solubility of any neutral oxalate (at 20 °C, 25 wt %). It was formerly used for the preparation of photographic developers and is employed today in the production of uranium in the extraction of the so-called yellow cake and in metal and textile treatment.

Potassium hydrogen oxalate [*127-95-7*], $KHC_2O_4 \cdot H_2O$, M_r 146.15, is found in many plants and was the first oxalate discovered in nature. LDLo, oral, human: 660 mg/kg.

Ammonium oxalate [*1113-38-8*], $(NH_4)_2C_2O_4 \cdot H_2O$, M_r 142.08. The anhydrous salt dissolves in water at 0 °C up to 2.27 wt % and at 100 °C up to 25.8 wt %. Ammonium oxalate is used in textile and leather processing as a replacement for oxalic acid, for the precipitation of rare earth elements, and in ore beneficiation (precipitation of heavy metals from acidic extracts).

Ammonium iron (III) oxalate [*29696-35-3*], $(NH_4)_3[Fe(C_2O_4)_3] \cdot 3H_2O$, M_r 428.08, forms emerald green crystals and is readily soluble in water and sensitive to light. It is used in the anodizing of aluminum and imparts, dependant on concentration, either yellow, gold, or brown colorations to aluminum. It is also employed in the treatment of other metals.

Sodium oxalate [*62-76-0*], $Na_2C_2O_4$, M_r 134.01, is easily prepared in high purity from oxalic acid and sodium hydroxide. Therefore, it is used as a titrimetric standard substance. The solubility in water at 0 °C is 2.6 wt % and at 100 °C is 6.3 wt %. Sodium oxalate is used for the production of super white pulp.

9.2. Organic Derivatives

(Cyanogen → Cyano Compounds, Inorganic, Chap. 5.)

Esters. Oxalic acid can be easily esterified by the usual methods. It forms both neutral (ROOC−COOR) and acidic esters (ROOC−COOH). The inherent acidity of oxalic acid is sufficient to catalyze the esterification in most instances. In some cases the esterification stops at the monoester stage. In this case anhydrous oxalic acid is used in preparation of the diester. Newer methods include the preparation from carbon monoxide and alcohols according to the Ube process (see Section 4.4) and the reaction of the easily accessible oxamide (see below) with alcohols in the presence of concentrated sulfuric acid [42].

Of industrial interest are the neutral esters, especially dimethyl, diethyl, and di-*n*-butyl oxalates. Except for the dimethyl ester which is a solid at room temperature they are all oily liquids with a faint odor, and thermally stable. Some esters can be distilled at atmospheric pressure without decomposition. The esters are readily soluble in alcohols, benzene, diethyl ether, acetone, and dioxane. Selected physical properties are presented in Table 3 (see next page). The neutral esters are good solvents for ethers and esters of cellulose (e.g., nitrocellulose) and for resins. They are therefore used for the production of special lacquers. Of greatest significance is the diethyl ester. The di-*n*-butyl ester is also used as a plasticizer. A further application results

Table 3. Physical properties of selected oxalates

Ester	M_r	*mp*, °C	*bp*, °C	d_4^{20}	CAS registry no.
Dimethyl	118.09	54	163.5	1.148 (54 °C)	[*553-90-2*]
Diethyl	146.15	−40.6	184.4	1.0785	[*95-92-1*]
Di-*n*-butyl	202.15	−29.6	245.5	0.9873	[*2050-60-4*]

from the ability of oxalic acid esters to easily undergo condensation reactions. Especially diethyl oxalate plays an important role in organic synthesis.

Oxamide [*471-46-5*], H_2N-OC-CO-NH_2, M_r 88.07, *mp* ca. 350 °C (decomp.), is sparingly soluble is water (0.3 g/L at 20 °C; 6 g/L at 100 °C).

Figure 5. Continuous production of oxamide
a) Reactor; b) Cooler; c) Sludge pump; d) Centrifuge; e) Dryer; f) Granulator

The most economic method for the production of oxamide is a one-step process by Hoechst that is based on a catalytic oxidation of hydrogen cyanide [43]:

$$2\,HCN + 1/2\,O_2 + H_2O \longrightarrow \begin{matrix} CONH_2 \\ | \\ CONH_2 \end{matrix}$$

$$\Delta H = -440\ \text{kJ/mol}$$

Oxamide

The flow chart is shown in Figure 5. A solution of copper nitrate in aqueous acetic acid is employed as the catalyst. The reaction is run at 65 °C and the yield is nearly quantitative. The oxamide that is insoluble in the catalytic solution precipitates at the bottom of the reactor and is pumped from there to a centrifuge, washed, dryed and, if desired, granulated. Without further treatment it has a purity of >99 % [44]. Using this method Enimont in Gela/Sicily, began a production plant in 1990 with a capacity of 10 000 t/a [45].

Oxamide can be converted to ammonium oxalate and oxalic acid by heating it for long periods with water; best results are obtained by the application of pressure. Oxamide has proved to be of great interest as a long-term fertilizer (→ Fertilizers, Chap. 4.4.). A single application is sufficient because the nitrogen is released gradually throughout the vegetation period in a form that the plant can easily use. A granular application form of oxamide is required. The poor aqueous solubility of oxamide guarantees that the fertilizer will not be washed away by rainfall and that it can be used in rice plantations. Oxamide can also be used as a starting material for chemical syntheses.

10. Toxicology [46,47]

Like other strong acids, oxalic acid has a local caustic effect. The compound is absorbed relatively well through the skin and very well through mucous membranes, so that contact with larger amounts can quickly lead to absorptive poisoning. Oral ingestion causes acute irritation and pain in the mouth, esophagus, and stom-

ach. Nausea, vomiting of blood, collapse, convulsions, irritability, and cramps (calcium precipitation) are known to occur. Premature coronary and/or circulatory arrest, and/or a kidney malfunction which results in anuria and uremia are possible. Eventual transition to polyuremia can occur. Death occurs in the coma or through kidney failure. Workers who had contact with a 5 % solution of oxalic acid without wearing protective gloves, complained of pains in their hands within a few days. Blood clots and damaged blood vessels and finally a very painful gangrene made amputation of the fingers necessary. With solutions of higher concentrations the superficial caustic effects become increasingly significant. Inhaling the vapors and/or dust evokes responses that range from irritation of the mucous membranes to rashes, headaches, overexcitability, and albuminuria. Persistent coughing, vomiting, and general weakness are signs of chronic effects. Skin rashes and brittle yellow fingernails are also known.

Intake of food containing higher quantities of oxalic acid should be avoided because of an impaired calcium absorption through the formation of insoluble calcium oxalate: 4 – 5 g oxalic acid can be deadly for humans because the precipitated calcium oxalate plugs the kidney channels. The normal excretion of oxalic acid from humans is 20 mg per day. Two-thirds of all kidney stones are composed of calcium oxalate. The toxicological levels are [48]:

LD_{50}, oral, rat	375 mg/kg
LDLo, oral, human	71 mg/kg
RTECS-no.	Ro 245000
EC-no.	607-006-00-8

1. Introduction

The chemical term oxidation, used here only in the sense of the take-up of oxygen by organic and inorganic materials, includes such differing processes as the combustion of organic material to obtain energy or synthesis gas, biological oxidation, industrial oxidations for the production of desired substances, the corrosion of metals, and the ageing of organic polymers.

Although each of these areas is very important industrially, in this article only an overview of the chemical and industrial fundamentals of the oxidation of hydrocarbons with atmospheric oxygen or with H_2O_2 or organic hydroperoxides, and of gas explosions will be given.

Atmospheric oxygen is by far the most important and also the cheapest oxidizing agent, since all others, for example, HNO_3, H_2SO_4 and SO_3/H_2SO_4 (oleum), Cl_2, MnO_2, CrO_3, as well as H_2O_2 and the organic hydroperoxides, must first be produced by using oxygen. However oxidations with molecular oxygen are usually considerably less selective than, for example, those with Cl_2 or HNO_3 and they generally require much higher investment, which becomes economically worthwhile only on exceeding a minimum capacity. This currently lies between 10^4 and 10^5 t/a, depending on the product.

Before World War II, organic materials were mostly oxidized with inorganic oxidizing agents and only rarely directly with O_2, since the most important products of industrial organic chemistry at that time were pharmaceuticals and dyes, for which only relatively small quantities of organic intermediates were required.

Exceptions included phthalic anhydride, for which heterogeneously catalyzed gas-phase oxidation of naphthalene was developed to an industrial level in Germany in 1916 (BASF) and in the United States (Bureau of Chemistry), and maleic anhydride, which has been obtained since 1928 by the Barret Co. in an analogous process involving the oxidation of benzene.

The age of plastics, with the mass production of polyamides, polyesters, polyurethanes etc., and the precursors necessary for them, only began after World War II.

Since about the mid 1970s ecological reasons became increasingly important in decreasing the use of inorganic oxidizing agents, although they are still used to some extent. An example is hydroquinone, which was previously produced by oxidation of aniline to *p*-benzoquinone with

© 2005 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim
10.1002/14356007.a18_261

MnO_2 and subsequent hydrogenation, but is now obtained from diisopropylbenzene by a process analogous to the Hock phenol process.

Table 1 gives an overview of the oxidation processes used today, whereby the data are predominantly obtained from [1]. Although the table is not intended to be comprehensive, it does give an impression of the importance which oxidation with O_2 has achieved in the meantime [2].

2. Thermodynamics; Stability of Hydrocarbons

Under normal conditions in the presence of O_2, CO_2 is the only thermodynamically stable carbon compound; at higher temperatures CO also becomes increasingly stable. Thus, in the presence of free O_2, all organic materials (living organisms, wood, coal, oil, synthetic polymers, solvents, etc.) are only metastable intermediates on the way to CO_2. The stability of all organic compounds in the presence of O_2 – and hence the yield of desired products in oxidations – therefore depends only on the kinetics of the reaction involved, i.e., on the prevailing conditions (temperature, effect of high-energy radiation, nature and concentration of catalysts or stabilizers (inhibitors) present, presence of other reaction partners, impurities, etc.).

Table 2 lists roughly estimated rates of typical reactions, and the linearly extrapolated time required for complete conversion.

3. Reaction Types

The oxidation of organic materials can be roughly divided into two groups:

Homolytic oxidation reactions are chain reactions of organic and inorganic compounds with oxygen involving radicals formed by homolytic cleavage of interatomic bonds. Explosions and combustion reactions, ageing of polymers and oils, and many industrial oxidation reactions in the homogeneous liquid and gas phases belong to this group. All types of organic compounds can be subjected to radical chain oxidation. Because many of these reactions proceed spontaneously even at low temperatures they are also called autoxidations.

Radicals recombine readily on surfaces. Therefore surface enlargement is a proven tool to stop radical reactions like explosions and flames.

Metal ions that can transfer only one electron, such as Co^{2+}/Co^{3+}, Mn^{2+}/Mn^{3+}, Fe^{2+}/Fe^{3+}, and Cu^{+}/Cu^{2+}, act as catalyst in the liquid or in the solid phase. The main function of the metal ions is splitting of the hydroperoxides. Substances which readily form radicals, such as phenols, many halogen compounds etc., can act either as catalysts or inhibitors, depending on their nature, concentration, and temperature.

Because radicals isomerize easily, and the resulting intermediates are usually more readily oxidizable than the starting hydrocarbons, homolytic oxidations generally have low selectivity. Only in several special cases homolytic oxidation can be performed with high selectivity. Examples include oxidation of cumene to the corresponding hydroperoxide, of alkylhydroanthraquinone to alkylantraquinone and H_2O_2, of *p*-xylene to dimethylterephthalate (DMT) or terephthalic acid (TPA), of aldehydes to acids and some other processes.

As an introduction [3–6] are recommended.

Heterolytic Oxidation Reactions. In heterolytic oxidation reactions an active oxygen compound (e.g., a peroxyacid, hydroperoxide, or O_2) or a metal ion in its high valence state (e.g., Pd^{2+} or V^{5+}) oxidizes the starting material in a two-electron transfer reaction. Normally, a stoichiometric amount of the oxidizing compound is used and a catalyst, for instance a complex of Mo, V, Ti has to be used.

The catalyst can be dissolved homogeneously in a liquid or be present in solid form. The reaction can take place in the liquid phase or in the heterogeneous gas phase.

Examples of heterolytic oxidations in the homogeneous liquid phase are the epoxidation of olefins with hydroperoxides, catalyzed by Mo complexes, and the oxidation of ethylene to acetaldehyde by Pd^{2+} complexes.

Examples of heterogeneous gas-phase reactions are the oxidation of benzene or butane/butene to maleic anhydride; and the oxidation of propene with mixed-oxide catalysts containing Mo to give acrylonitrile (or acrolein and

10^{22}	10	ca. 10^{-2} s	heterogeneously catalyzed hydrocarbon oxidations
10^{24}	10^3	ca. 10^{-4} s	explosions; ion reactions

[a] Pure hydrocarbons contain ca. 6×10^{21} molecules per cubic centimeter.
[b] 1 mol/L corresponds to ca. 6×10^{20} molecules per cubic centimeter.
[c] 1 year $\approx$ 8760 h $\approx 3.15 \times 10^7$ s.

acrylic acid) and with Pd catalysts to give allyl acetate.

Unlike radical autoxidations, heterolytic oxidations proceed via defined complexes and are therefore, in principle, very selective.

For an introduction and review see [4] and [16]; further literature: [12], [17–22].

4. Homolytic Oxidation

4.1. Historical Development; Reaction Mechanism; Radical Reactivity

An extensive study of the history of homolytic oxidation is still missing. Short reviews of the historical development of knowledge of homolytic oxidation can be found, for example, in [3, pp. 1 – 14], [5], and, with emphasis on the development of homogeneous gas-phase oxidation, in a publication by SHTERN [10].

The development of concepts of oxidation began with the introduction of the phlogiston the-

ory in the 17th century by BECHER and STAHL and its disproving in 1773 by LAVOISIER. The development of theories for the oxidation of organic materials started in 1897 with ENGLER's proposal that the first step in the oxidation of an olefin consists in the addition of one O_2 molecule to a C=C double bond forming a four membered ring (see Fig. 1 a). Later on this theory was called "moloxide"theory by STAUDINGER. Despite the fact, that a growing number of arguments could be brought forward against the moloxide theory, it was accepted until 1939. In this year CRIEGEE and coworkers could unambiguously show, that in the first stage of the oxidation of an olefin a hydroperoxide is formed (see Fig. 1 b). Already in 1900 BAEYER and VILLIGER had isolated perbenzoic acid as an intermediate in the oxidation of benzaldehyde to benzoic acid.

Another problem that was difficult to understand for a long time was the S-shaped slope of the velocity curve of the oxidation of hydrocarbons (see Fig. 2). Since the few radicals known to the late 1920s were very reactive and therefore short lived, nearly nobody could imagine that radicals could significantly participate in the slow oxidation of hydrocarbons. CHRISTIANSEN had therefore developed in 1924 the concept of an "energy chain reaction" with the inclusion of a "hot" molecule.

Figure 3. Course of a methane explosion and a hydrogen explosion in a sealed vessel (stoichiometric mixture with O_2) [23, p. 10]

In 1927 BÄCKSTRÖM opposed this idea with the concept of a radical chain reaction, on the grounds of the high quantum yield in photochemical oxidations.

A mathematical solution to a similar problem – the reaction of H_2/O_2 mixtures – was found by SEMENOV in 1926 who based his theory on the work of BODENSTEIN and NERNST. The latter developed the theory of the unbranched chain reaction taking the experimental results of BODENSTEIN, who studied the photochemically induced Cl_2/H_2 reaction in 1913 (Scheme I). In 1926 SEMENOV first proposed the theory of the branched chain reaction describing mathematically the pressure rise in the H_2/O_2 explosion (Scheme II, see [7–10]).

Scheme I. Unbranched radical chain reaction

Initiation

$Cl_2 + h\nu \longrightarrow 2\,Cl\cdot$ (1)

Propagation

$Cl\cdot + H_2 \longrightarrow HCl + H\cdot$ (2)

$H\cdot + Cl_2 \longrightarrow HCl + Cl\cdot$ (3)

Termination

$2\,H\cdot + (wall) \longrightarrow H_2 + (wall)$ (4)

$2\,Cl\cdot + (wall) \longrightarrow Cl_2 + (wall)$ (5)

$H\cdot + Cl\cdot + (wall) \longrightarrow HCl + (wall)$ (6)

Scheme II. Branched radical chain reaction

Inititiation

$H_2 + O_2 \longrightarrow 2\,HO\cdot$ (7^r)

Propagation

$HO\cdot + H_2 \longrightarrow H_2O + H\cdot$ (8^r)

$HO\cdot + \cdot OH \longrightarrow HOO\cdot + H\cdot$ (9^r)

$\cdot O\cdot + H_2 \longrightarrow \cdot OH + H\cdot$ (10^r)

Branching

$H\cdot + O_2 \longrightarrow HO\cdot + \cdot O\cdot$ (11^r)

$HOO\cdot \longrightarrow HO\cdot + \cdot O\cdot$ (12^r)

Termination

$H\cdot + \cdot OH + (wall) \longrightarrow H_2O + (wall)$ (13^r)

$H\cdot + \cdot H + (wall) \longrightarrow H_2 + (wall)$ (14^r)

$\cdot O\cdot + \cdot O\cdot + (wall) \longrightarrow O_2 + (wall)$ (15^r)

Figure 4. Relationship between E_a, E, E_o, and ΔH for exothermic ($E_{a\rightarrow}$) and endothermic ($E_{a\leftarrow}$) reactions

In the early 1930s SEMENOV was able to prove mathematically that the pressure rise in the autoxidation of hydrocarbons could also be explained using the model of a branched chain reaction. Because of the long induction period and the slow rise of the pressure, compared with the

very fast H_2/O_2-reaction, he called this reaction "degenerate" branched chain reaction (see Fig. 3 and [9, pp. 317ff and pp. 438ff]).

Confirming the findings of CRIEGEE, FARMER in 1941 – 1942 was the first to propose the chemical radical chain mechanism of the homolytic oxidation of hydrocarbons (Scheme III).

Scheme III. Hydrocarbon oxidation (degenerate branched radical chain reaction)

Initiation

$R\text{–}H + O_2 \longrightarrow R\cdot + \cdot OOH$ (16^r)

$R\text{–}H + O_2 + H\text{–}R \longrightarrow R\cdot + HOOH + \cdot R$ (17^r)

$R\text{–}R + h\nu \longrightarrow R\cdot + \cdot R$ (18^r)

Propagation

$R\cdot + O_2 \longrightarrow ROO\cdot$ (19^r)

$R\text{–}H + ROO\cdot \longrightarrow R\cdot + ROOH$ (20^r)

$ROO\cdot + C{=}C \longrightarrow ROO\text{–}CR_2\text{–}C(R_2)\cdot$ (21^r)

Branching

$ROOH\,(ROOR) \longrightarrow RO\cdot + \cdot OH\,(+\cdot OR)$ (22^r)

$ROOH + ROOH \longrightarrow ROO\cdot + H_2O + RO\cdot$ (23^r)

$ROOH + ROH \longrightarrow RO\cdot + H_2O + RO\cdot$ (24^r)

Termination

$R\cdot + R\cdot \longrightarrow R\text{–}R$ (25^r)

$RO\cdot + R\cdot \longrightarrow ROR$ (26^r)

$ROO\cdot + ROO\cdot \longrightarrow ROOR + O_2$ (27^r)

$ROO\cdot + R\cdot \longrightarrow ROOR$ (28^r)

The essential differences between the relatively slow hydrocarbon oxidation and the very fast oxygen – hydrogen reaction (see Fig. 3) and similar branched radical chain reactions are:

1) In the hydrocarbon oxidation, hydroperoxide formation occurs prior to the branched hain reaction. Hydroperoxide formation takes place by an unbranched radical chain reaction according to Reactions (19^r) and (20^r) (propagation in Scheme III).
2) The chains branch by decomposition of the alkylhydroperoxide molecule. However, molecules react orders of magnitude more slowly than radicals (therefore "degenerate" chain branching). Only at high temperatures branching of chains occurs via peroxy radicals in hydrocarbon oxidations. But even then these oxidations are not as fast as the H_2/O_2-reaction (see Fig. 3 and Section 4.5).
3) In large hydrocarbon radicals the energy absorbed on dissociation is dissipated rapidly over the entire radical by atomic vibrations. The radical thus loses a considerable portion of reactivity. This behavior is particularly marked for radicals from aromatic compounds and olefins in which the unpaired electron (odd electron) is additionally stabilized by the π-electron system.
4) Because of their lower reactivity these radicals have a longer lifetime than the more reactive radicals.
5) Because of the longer lifetime and the ability to rapidly dissipate energy, the large radicals can readily recombine in binary collisions (chain termination). The recombination of small radicals (e.g., $H\cdot + \cdot H$ or $H\cdot + \cdot OH$) occurs only in the much rarer three-body collisions or at the wall because of the need to remove the bond energy liberated.

Bond Strength and Radical Reactivity. Radical chain reactions essentially occur through the attack of a radical at a covalent bond such that an existing bond is broken and a new one formed:

$R_3C\text{–}H + X\cdot \longrightarrow R_3C\cdot + H\text{–}X \; -\Delta H$ (29^r)

In such homolytic substitution reactions, a radical is more reactive the greater the value of $-\Delta H$, i.e., the greater the difference between the bond energies according to:

$$\Delta H_{(H-X)} - \Delta H_{(C-H)} = -\Delta H \text{ kJ/mol} \quad (1)$$

According to the rule of POLANYI and EVANS, more precisely formulated by SEMENOV [9, p. 26 ff], from the equation:

$$E_a = 48 + 0.25\,(-\Delta H) \text{ kJ/mol} \quad (2)$$

the activation energy E_a of an exothermic reaction is lower and the reaction faster the greater the value of $-\Delta H$ (see Figs. 4 and 5).

Figure 5. Dependence of the activation energy E_a on the enthalpy of reaction ΔH for exothermic radical exchange reactions of type $A - B + C\cdot \rightarrow A\cdot + B - C$ [7–9]
The reactions investigated by POLANYI and EVANS lie in the shaded area

In Figure 6 dissociation energies for various types of bond are shown. The following is noted:

1) The attack of a radical at a C – H bond takes place more easily and faster the lower the energy of the bond and the greater the energy of the attacking radical. The reactivity of C – H bonds increases with decreasing bond energy:
   Vinyl ≈ phenyl < primary < secondary < tertiary < allyl < cumyl < diallyl
2) The first members of homologous series (e.g., methane, ethylene, benzene) have particularly high C – H bond energies and are correspondingly stable towards attack by radicals. In alkanes the energy of the primary C – H bonds decreases with increasing chain length. Alkenes are either attacked at the allylic C – H bond or the radicals add to the C=C double bond.
3) The hydroxy, alkoxy, and acyloxy radicals can abstract a H atom from all C – H bonds. The peroxy radicals, in contrast, exhibit a similarly high reactivity only towards C – H bonds of hydrocarbons, alcohols, and aldehydes that lie below the tertiary C – H bond of isobutane in the energy scale. With C – H bonds of compounds which lie above isobutane, these radicals react much more slowly, but much more selectively (see Section 4.4.1, Tables 9, 10).
4) Through the cleavage of the comparatively weak O – O bond in peroxides the highly active HO · and RO · radicals are formed.

According to Figure 6 the C – H bond of the aldehyde group is less reactive than the allylic C – H bond in olefins or the tertiary C – H bond of cumene. However, in reality aldehydes are much more reactive than these hydrocarbons because they can be oxidized at much lower temperatures than e.g., cumene or butene (see Table 3, last line). There are three reasons for this confusing phenomenon:

1) The data in Figure 6 originate from measurements in the gas phase. In the case of hydrocarbons these data can be applied to the reactivity in the liquid phase without complications because in the liquid phase hydrocarbon molecules interact with one another only weakly and are not altered chemically until they are oxidized. But in the case of aldehydes these data are misleading, because aldehydes form addition products with polar compounds like water, alcohols, and acids in the liquid phase. In the addition product the remaining C – H bond of the aldehyde group is strongly activated by either two OH groups or one OH and one O–R group at the same C-atom.
2) Peroxyacyl radicals are much more reactive than peroxyalkyl radicals in cleaving a C – H bond to gain a H-atom in order to stabilize to the corresponding peroxy acids.
3) Peroxy acids decompose much faster to radicals than alkyl hydroperoxides (see Section 4.4.1).

Initiation; Induction Period; Peroxide Formation. Small molecules such as H_2, CH_4, and NH_3 normally exist as gases. Because of the stable bonds, which necessitate high dissociation energies, and because of the weak interactions between the gas molecules, these types of molecule only react with oxygen at high temperatures, if no catalysts or initiators are present. At low temperatures their mixtures with oxygen are metastable in the absence of catalysts.

In the autoxidation of higher hydrocarbons the situation is quite different, especially in the liquid and solid phase. Because of intermolecular interactions and the relatively low bond energies of many C – C and C – H bonds, radicals are formed relatively rarely, but continually, even at low temperatures. This may occur by reaction with O_2 (Reactions 16^r or 17^r) or by concentration of the thermal vibration energy into one bond (cf., the lowering of the ignition temperature for gas explosions from ca. 600 °C for methane to ca. 200 °C for decane, see Table 15). The rate of radical formation is increased drastically by high-energy radiation (sunlight) and heat. In most cases these radicals recombine – above all in the liquid or solid phase, where the mobility of the molecules and their fragments is severely limited as a result of the forces of interaction (solvent cage). However, if oxygen is present, it competes with the simple radical recombination (Reaction 25^r) because of its diradical structure (Reaction 19^r). These types of radical recombination take place without activation energy and are therefore very fast. This mechanism is the

Figure 6. Dissociation energies of various bonds [9, p. 16 ff.]

cause of the ageing of organic materials in the presence of oxygen even at low temperatures. It is also the mechanism of initiation of autoxidation.

Although radical chains are continuously initiated even at low temperatures, the reaction does not exceed a uniform low rate as long as more radicals are destroyed than are formed. This is the cause of the induction period, which is always exhibited by uncatalyzed autoxidation reactions. In particular hydroperoxides accumulate during this induction period as active intermediates, which are formed in an unbranched chain reaction according to Reactions (19^r) and (20^r).

Dangerous peroxide build-up can occur in olefin-containing liquids, since peroxy radicals also add easily to double bonds according to Reaction (21^r). Because oxygen generally reacts much faster with the alkylperoxyalkyl radicals formed than the olefin, copolymeric peroxides are formed in this way. Because of the missing OH group, these are considerably more stable than hydroperoxides and can therefore accumulate in large quantities. At higher temperatures they can decompose explosively. Because the common reagents for peroxide detection are mostly sensitive to hydroperoxide, these polyperoxides often remain undetected. For more details, see [24–27].

Hydroperoxides also accumulate in paraffins, glycol ethers, and other nonvolatile organic compounds on exposure to air. These can initiate rapidly accelerating oxidation reactions even at moderate temperatures. Cleaning cloths soaked with linseed oil can even ignite at room temperature. The self-ignition temperature of paraffins, surfactants, glycol ethers, and similar substances drops below 100 °C if, for example, insulating material with a large surface area, such as rock wool which has been moistened with them has been lying for a few days in the air.

The induction period can be shortened or completely eliminated by the addition of peroxides or other radical-forming reagents, or through irradiation.

Table 3. Oxidizability, absolute chain propagation rate k_p, and chain propagation rate relative to cumene $(k_p)_{rel}$ for various organic compounds at 30 °C , [4, p. 19], [5, p. 35]

Compound	$(k_p/\sqrt{2k_t})\cdot 10^3$, $mol^{-0.5}\,s^{-0.5}$	k_p, $L\,mol^{-1}\,s^{-1}$	$(k_p)_{rel}$

Benzaldehyde	290	33 000	

Termination; Inhibition. Radical chain reactions can be slowed down or stopped by reducing the concentration of active intermediates, for instance by enhancing radical recombination reactions.

In homolytic gas- and liquid-phase oxidations, solid surfaces are the most effective radical scavengers. Fillings or packings made from thin tubes (capillaries) or Raschig rings are used overall in industry as flame and explosion barriers, and certain inorganic dusts (e.g., ammonium phosphate) are among the most effective fireextinguishing agents.

Organic antioxidants (e.g., phenols, thiols, amines) act in different ways. Phenols, for instance, are transformed by active radicals into low energy radicals, which subsequently add other active radicals forming stable products. Thiols are oxidized by hydroperoxides to sulfoxides whereby the hydroperoxides are reduced to alcohols. In these reactions the organic antioxidants are, however, gradually consumed. Once they have been consumed, the autoxidation continues at the rate it would have in the unstabilized substance (see Fig. 7); for more details, see Section 4.4.3. An introduction to organic stabilizers and antioxidants can be found in [3]; fire and explosion protection are described in [23], [28–36].

Figure 7. Typical autoxidation curves in the absence and presence of antioxidants [3, p. 4]
a) Absence of antioxidant; b) *x* parts antioxidant; c) 2 *x* parts antioxidant

Rise in the Reaction Rate; Final Conversion. As soon as the peroxide concentration has exceeded a critical value – which depends on the nature of the compound to be oxidized, the state of aggregation, the presence or absence of catalysts, and the temperature – the overall rate of radical formation by peroxide decomposition (Reactions 22^r to 24^r) begins to exceed that of radical destruction (Reactions 25^r to 28^r). From this point, the overall reaction rate increases ex-

ponentially to a maximum, which is reached at an early stage of the overall reaction.

Afterwards the reaction rate slows down to zero. In the oxidation of hydrocarbons the reaction normally ceases long before the starting material is completely consumed. One reason for this behavior is the dilution of the reaction mixture by the end products formed, mainly water and lower carboxylic acids such as acetic acid, the latter being very resistant against oxidation. In the presence of metallic ions as catalysts, water and carboxylic acids act as catalyst poisons because they are stronger complexing agents than hydroperoxides (see Section 4.4.2). Raising the temperature can revive the reaction for a more or less short time.

High starting material conversions are, however, only rarely desired in homolytic oxidations because the product selectivity decreases rapidly with increasing conversion due to secondary reactions. Frequently, starting material conversions of 10 – 30 %, sometimes even only 1 %, are aimed for. (For more details see Section 4.2.)

Hydroperoxide Decomposition. The decomposition of hydroperoxides is the main source of radicals during the entire reaction (Scheme III, Reactions 22^r to 24^r).

The thermal decomposition of peroxides has activation energies of between 120 and 164 kJ/mol. These are the highest activation energies of the reactions shown in Scheme III.

The hydroperoxide decomposition therefore determines the temperature range for the oxidation of organic compounds. Temperature ranges for liquid-phase oxidations are as follows: aldehydes: up to 80 °C; olefins and cumene: up to 130 °C; aliphatics, alkylaromatics, alcohols, ketones, esters: 80 to 200 °C.

4.2. Kinetics of Autoxidation

Kinetic measurements, in particular with respect to individual elementary reactions, are associated with particular difficulties and uncertainties in radical chain reactions because of the great number of parallel and secondary reactions and the normally very low concentration of the reacting compounds. Nevertheless, many insights into the course of the reaction could be obtained, for example, by

1) Following the pressure rise in gas-phase oxidations
2) Investigation of the peroxide decomposition in hydrocarbons
3) Simultaneous oxidation (cooxidation) of different compounds
4) Oxidation in the presence of a tertiary hydroperoxide
5) By using specific analytical methods: ESR, chemiluminescence, and UV absorption for radicals; liquid chromatography for hydroperoxides and nonvolatile compounds; gas chromatography for the stable, volatile products etc., and many other methods.

The main problem is still, however, the quantitative determination of all components present in a reaction mixture. For example, active intermediates react further after the sample has been taken, so that the composition of the sample changes rapidly. For low-conversion reactions, which are required for the precise determination of the kinetics, the sensitivity limits of all analytical methods are quickly reached. For a review of experimental methods for the determination of the kinetics of radical chain oxidations see [6], and for analytical methods for peroxide determination see [37].

Under mild conditions (temperature < 100 °C and sufficient oxygen, i.e., for a liquid-phase reaction: O_2 partial pressure > 10 kPa, for a gas-phase oxidation: O_2 excess) the rate of oxygen conversion is only determined by Reaction (20^r) in the case of the oxidation of hydrocarbons, since Reaction (19^r) is very fast and the concentration of R · is very small. The following equation is therefore valid:

$$-\frac{\mathrm{d}\,[\mathrm{O_2}]}{\mathrm{d}t} = k_\mathrm{p}\,[\mathrm{ROO^{\cdot}}]\;[\mathrm{RH}] \tag{3}$$

Since a kinetic equilibrium (steady state) is established very rapidly after initiation of the radical formation and radical scavenging reactions, and because only Reaction (27^r) plays a role as a chain termination reaction at sufficient O_2 supply, the following is valid:

$$u_\mathrm{i} = u_\mathrm{t} = 2k_\mathrm{t}\,[\mathrm{ROO^{\cdot}}]^2 \tag{4}$$

where u_i = rate of chain initiation and u_t = rate of chain termination. Inserting Equation (4) into (3) gives:

$$-\frac{\mathrm{d}\,[\mathrm{O_2}]}{\mathrm{d}t} = \frac{k_\mathrm{p}}{\sqrt{2k_\mathrm{t}}}\,[\mathrm{RH}]\cdot\sqrt{u_\mathrm{t}} \tag{5}$$

Equation (5) is only valid for low conversions as the secondary reaction products formed at higher conversions are generally more readily oxidized than the starting hydrocarbon. The expression $k_\mathrm{p}\,/\,\sqrt{2k_\mathrm{t}}$ is referred to as the "oxidizability", since it indicates how much faster one organic compound is oxidized than another. Table 3 lists values for the oxidizability as well as k_p and relative k_p (based on cumene) values for various hydrocarbons. Under mild oxidation conditions, the value of k_p increases in the following order: *n*-alkanes < isoalkanes < alkylaromatics < alkenes < alkynes ≈ styrene derivatives ≪ aldehydes.

If, however, the oxidation rates of alkanes are compared under more severe conditions (temperature > 120 °C) where the hydroperoxide decomposition determines the reaction rate, then the order of overall oxidation rate is as given in Table 4 and Figure 8.

Table 4. Relative oxidation rate of various *n*-alkanes , [15, p. 94]

n-Alkane	Relative oxidation rate [mol O_2 (mol alkane)$^{-1}$ time^{-1}]
Ethane	0.001
Propane	0.1
Butane	0.5
Pentane	1.0
Hexane	7.5
Octane	200
Decane	1380

It can be seen that the overall oxidation rate increases sharply both with increasing chain length and with decreasing branching. The reasons for this are:

1) In the series primary → secondary → tertiary C – H bonds, the rate of formation of the hydroperoxides increases dramatically, but their rate of decomposition decreases equally drastically. The secondary hydroperoxides are formed more slowly than tertiary hydroperoxides but decompose considerably faster, so that the lower rate of formation is more than compensated for. Therefore, under these conditions, hydrocarbons with secondary C – H bonds are oxidized faster than hydrocarbons having tertiary C – H bonds.
2) The number of secondary H atoms per molecule increases with decreasing branching. All secondary C – H bonds in an alkane are attacked equally rapidly.

Tables 5, 6, 7, 8 list some literature values for the collision factor A, activation energy E_a and rate constant k for the initiation of the elementary reaction, peroxide decomposition (branching), propagation, and termination [5–9], [24] (Because autoxidation is generally initiated by the decomposition of added peroxides, peroxide decomposition frequently is designated "initiation" in the literature, which is incorrect and may lead to confusion.)

The following points may be made:

1) According to Equation (5) the rate of O_2 take-up in the initial phase of an oxidation is only proportional to the hydrocarbon concentration and is independent of the O_2 concentration under mild reaction conditions.
2) The k value of Reaction (19$^\mathrm{r}$) is estimated to be 10^7 to $> 10^9$ L mol^{-1} · s^{-1} (corresponding to 10^{-14} to $> 10^{-12}$ cm^3 molecule^{-1} · s^{-1}) at $E_\mathrm{a} \approx 0$ kJ/mol [4]. It is orders of magnitude faster than Reaction (20$^\mathrm{r}$), which therefore determines the propagation rate. Because of its high rate, Reaction (19$^\mathrm{r}$) is generally controlled in the liquid phase under industrial conditions by O_2 diffusion.
3) The number of repetitions of Reactions (19$^\mathrm{r}$) and (20$^\mathrm{r}$) is referred to as the kinetic chain length ν. It is given by the ratio of the propagation rate to the termination rate. Because of the stationary state $u_\mathrm{i} = u_\mathrm{t}$, it follows that:

$$\nu = \frac{u_\mathrm{p}}{u_\mathrm{t}} = \frac{k_\mathrm{p}}{\sqrt{2kt}\,\sqrt{u_\mathrm{i}}}\cdot[\mathrm{RH}] \tag{6}$$

With increasing rate of radical formation and radical concentration, i.e., with intensification of the reaction conditions (e.g., by raising the temperature and/or initiator concentration), the chain length becomes shorter. Under mild reaction conditions ν can exceed 1000. Under industrial conditions it is usually ca. 10.
4) The hydroperoxide decomposition has the highest activation energy. The values given are extrapolated to infinite dilution and are

Relative oxidation velocity	1	12	60	560	1580

[a] (27^r): ROO· + ROO· ⟶ ROOR + O_2; $u_t = k_t \cdot [ROO\cdot]^2$; $k_t = A_t \cdot \exp(-E_{a,t}/RT)$.
[b] The compound name stands for the secondary or tertiary peroxy radical, respectively.

therefore valid for the uncatalyzed, unimolecular, thermal decomposition. Under normal oxidation conditions (no metal catalyst, but typical concentrations of radicals, hydroperoxides, alcohols, acids, and other substances with an accelerating effect), the activation energies for the hydroperoxide decomposition are considerably lower, especially in the liquid phase. Nevertheless, they are still higher than those of the other reactions. The hydroperoxide decomposition therefore determines the temperature range of the oxidation.

5) With progressing oxidation an increasing number of intermediates are formed (aldehydes, alcohols, ketones) that are more readily oxidized than the starting hydrocarbon. These products form, on the one hand, other hydroperoxides and peroxy radicals, some more labile, some more stable, and on the other hand some of these products and their radicals catalyze the decomposition of the hydroperoxides.

This has several consequences:

a) The reaction rate increases until it reaches its maximum with the appearance of aldehydes.
b) The O_2 uptake is accelerated to a greater extent than the consumption of the starting material owing to formation of the more readily oxidizable intermediates.
c) The products formed from these intermediates – principally lower carboxylic acids – are more stable to oxidation than the starting hydrocarbons and, in the case of metal-catalyzed autoxidations inhibit the peroxide decomposition with increasing concentration. The rate of radical formation thus decreases gradually to zero and the reaction stops before the starting material is completely consumed.

6) Aldehydes are particularly readily oxidized (see Sections 4.1 and 4.4.1).

4.3. Differences between Liquid- and Gas-Phase Autoxidations

In principle, autoxidations proceed with the same mechanism in the liquid and gas phases. However, to achieve comparable reaction rates, the temperature in the gas phase must be 100 – 200 °C higher than in the liquid phase because of the weaker interactions between the molecules (in the gas phase nearly no hydrogen bonds are formed, no metallic catalysts are present, etc.).

Above 250 °C paraffins increasingly react with oxygen in a first step to olefins and hydrogen peroxide. Hydrogen peroxide is far more stable than alkylhydroperoxides against splitting of the O – O bond. Additionally, above 250 °C peroxy radicals increasingly do not stabilize to form hydroperoxides, but isomerize and/or split directly to products such as aldehydes plus RO•. But these reactions require higher activation energies than decomposition of hydroperoxides. Therefore, in the region 350 – 450 °C, depending on the hydrocarbon, the reaction velocity decreases with increasing temperature (region of negative temperature coefficient). At higher temperatures the reaction rate rises again with temperature.

The effect of material and heat transport is of considerable importance for the different pathways followed by homolytic oxidations in the liquid or gas phase.

In the liquid phase, heat transfer is good and the oxidation rate is mostly limited by oxygen transport from the gas phase. In the gas phase mass transfer does not limit the oxidation rate but heat transfer is poor due to the low mass of the gas. The oxidation reaction can therefore readily turn into a thermal explosion due to insufficient heat removal.

Table 9. Relative rate of Reaction (20^r)∗ as a function of the nature of the attacked C – H bond

R–H	C–H	prim.	sec.	tert.
2-Methylpentane	u_{rel}	1	30	300

More details on gas phase oxidation are given in Section 4.5. A detailed account of the differences between gas- and liquid-phase oxidations can be found in, for example [6, pp. 442 – 495].

4.4. Homolytic Oxidation in the Liquid Phase

4.4.1. Secondary Reactions of Radicals, Peroxides, and other Intermediates

It is only possible here to go briefly into the secondary reactions of the intermediates and radicals that are important for the understanding of radical chain oxidations by means of selected examples. For further information see [37], [54].

Reactions of Alkyl and Aralkyl Radicals. The most important reactions of these radicals are:

1) Addition of O_2 (Reaction 19^r).
2) Recombination with other radicals (termination Reactions 25^r, 26^r, 28^r).
3) Addition to C=C double bonds.
4) Isomerizations (Reactions 30^r to 33^r).

Because Reaction (19^r) is so rapid, even a low O_2 concentration (O_2 partial pressure in the gas phase 25 kPa) is sufficient to make the concentration of hydrocarbon radicals so small that they can practically no longer participate in recombination reactions.

In industry, however, oxidation reactions are mostly run with O_2 off-gas concentrations near to zero. The upper part of the bubble column is thus deficient in O_2, so that the concentration of hydrocarbon radicals increases, and radical recombination reactions can occur in this region. Thus in practically all industrial autoxidations radical trapping products formed according to Reactions (25^r) to (28^r) are found.

Table 10. Relative rate of Reaction (20^r)∗ as a function of the substituent X at the same carbon atom bearing the attacked C – H bond

X–R–H	X:	H	OOH	OH
	u_{rel}:	1	9.5	12
Ethylbenzene-X [(1-X,1-phenyl)ethane]				
	u_{rel}:	1	13	6.3
n-decyl-X				

∗ Reaction (20^r) R – H + R'OO• ⟶ R• + R'OOH

The addition of alkyl radicals to C=C double bonds occurs in olefin oxidations and acts as an

initiation reaction for radical polymerization in the oxygen-deficient regions of the bubble column.

Radicals that are stabilized by π-electron systems isomerize very readily; examples include Reactions (30^r) to (33^r):

(30^r)

Yield 100 %;
no polymeric peroxide

(31^r)

Yield 100 % polyperoxide;
no hydroperoxide

(32^r)

Yield 100 % hydroperoxide

(33^r)

Reaction (33^r) involves a doubly activated CH_2 group as is present in, for example, linolenic acid derivatives. Double bond systems of this type isomerize almost completely during oxidation to give conjugated double bonds. With an adequate O_2 supply they react – like all olefins – to form copolymeric peroxides. With a deficiency of O_2 they react to give homopolymers (principle of self-drying oil paints).

Reactions of Peroxy Radicals. The most important reaction of the peroxy radical is H abstraction (Reaction 20^r). The relative rates of attack of R–OO · on primary, secondary, and tertiary C–H bonds and on C–H bonds which have another substituent (OH, OOH) on the same C atom are given in Tables 9 and 10. For example, alkylperoxy radicals react with the primary, secondary, and tertiary C–H bonds in 2-methylpentane in the ratio 1/30/300.

Because of their comparatively low reactivity the ROO · radicals can accumulate in detectable concentrations (unlike, for example, HO ·, R ·, RO ·). In the oxidation of cumene, radical concentrations of up to 8×10^{-5} mol/L, corresponding to 5×10^{16} molecules/cm^3, were detected by ESR. Peroxy radicals therefore frequently recombine, for example by Reactions (34^r, Russel reaction) and (35^r).

(34^r)

Russel mechanism (for primary and secondary ROO ·)

(35^r)

Lacking H atoms at the C-atom that binds the peroxy group, tertiary ROO · radicals cannot be stabilized in the same simple way as primary and secondary peroxy radicals (see Reaction 34^r). They generally recombine to give tetroxides, which subsequently decompose forming very stable di-*tert*-alkyl peroxides (Reaction 35^r) or *tert*-alkoxy radicals. The latter may either form tertiary alcohols or decompose further with cleavage of the carbon framework to form ketones, aldehydes, alkanes, or other decomposition products:

(36^r)

Because reactions of type (36^r) have high activation energies, the overall reaction of the recombination of tertiary ROO · radicals proceeds in general with high activation energy (see Table 8).

Rate constants and activation energies for the recombination of primary, secondary, tertiary, and allylic ROO · radicals are listed in Table 8. The oxidation rate is inversely proportional to these chain termination rate constants (see Eq. 5). Therefore, under mild conditions (ca. 100 °C) autoxidations of primary and secondary C – H bonds are slower than those of tertiary C – H bonds, not only because of their higher bond energies but also because of the higher recombination rates of primary and secondary ROO · radicals.

In contrast, hydrocarbons with allylic C – H bonds such as ethylbenzene and tetralin are oxidized faster than those with tertiary C – H bonds. Nevertheless, because of the higher recombination rates of allylic ROO · radicals, addition of the corresponding hydrocarbons does not enhance, but strongly hinders the autoxidation of tertiary C – H bonds under mild conditions. For example, the rate of oxidation of cumene is reduced by two thirds by the addition of 3 % tetralin because the rapidly formed tetralyl peroxy radicals capture the cumyl peroxy radicals, which are formed more slowly. Ethylbenzene has an analogous effect.

Peroxy radicals also add readily to C=C double bonds, forming either epoxides and alkoxy radicals (Twigg mechanism), or polyperoxides and their decomposition products (epoxides, aldehydes, alcohols, and ketones) (Mayo mechanism).

(37r)

They can also add to ketones (radical variant of the Baeyer–Villiger reaction) to give esters or lactones.

(38r)

More often, attack at the C – H bond α to the keto group occurs, followed by chain cleavage (or ring-opening) and oxidation to carboxylic acids:

(39r)

Reactions of Hydroperoxides, Dialkylperoxides, and Peroxyacids. The stability of hydroperoxides depends on (1) the structure, (2) the surrounding medium, and (3) the active components in this medium.

For aliphatic hydroperoxides, the stability decreases in the order: tertiary > secondary > primary. Electron-withdrawing groups (–C≡N, –COOR) have a destabilizing effect, and methyl groups a stabilizing one. Hydroperoxides in which the HOO-group is in a position α to a double bond or an aromatic ring (resonance stabilization) are fairly stable. Because C – H bonds in such α-positions are weakened due to the resonance stabilization of the incipient radical, these types of hydroperoxide are formed at lower temperatures than others, and can be obtained in high yields (e.g., cumene hydroperoxide).

The homolytic decomposition of hydroperoxides is catalyzed by compounds that form hydrogen bonds, i.e., by the hydroperoxides themselves and by alcohols and carboxylic acids (Reactions 23r, 24r, 40r). The reason is that the leaving group H_2O is preformed by these O· · ·H bridges. Table 5 lists kinetic data for the monomolecular decomposition of peroxide in highly dilute solution (see Reaction 22r). In hydrocarbons the decomposition rate depends strongly on the C–H dissociation energy of the

solvent: the lower the C–H dissociation energy, the faster the decomposition (catalysis by metals, see Section 4.4.2).

Radicals also catalyze hydroperoxide decomposition. Accordingly, hydroperoxides can be stabilized by the addition of radical scavengers.

Because of their acidic character, peroxyacids catalyze their own decomposition much more strongly than the alkyl hydroperoxides:

The acyloxy radicals formed are more reactive than the alkyl peroxy radicals. They can react in different ways:

Normally, Reaction (44ʳ) is the preferred one. But if there are not sufficient molecules with active C–H bonds available, that can be attacked by the acyloxy radical in order to stabilize the radical as a carboxylic acid, Reaction (45ʳ) becomes important (formation of CO_2). Reaction (45ʳ) seems to be important also in the case of aromatic acyloxy radicals. There the odd electron is attracted by the π-electron system of the aromatic ring which leads to radical isomerization, and subsequently splitting into a phenyl radical and CO_2. Reactions (46ʳ) to (48ʳ) are of minor importance. Only in the presence of copper ions, a modified version of Reaction (48ʳ) gains importance (see Reaction 87ʳ).

Cleavage by Mineral Acids. Mineral acids protonate peroxides and thus induce their decomposition. The best known example is the Hock rearrangement of cumene hydroperoxide to give phenol and acetone:

Another industrially important example is the oxidation of *p*-xylene to terephthalic acid, catalyzed by $CoBr_2$ in acetic acid (see Reaction 92[r]). Oxidations of alkylaromatics in which mineral acids such as HBr can be formed only proceed at a satisfactory rate if it is ensured that the concentration of the mineral acid remains low. Otherwise, phenol, which acts as an oxidation inhibitor, may be formed by acidic hydroperoxide cleavage.

Reactions with Bases. Bases react with primary and secondary hydroperoxides as follows (PRITZKOW believes that these findings are artefacts, caused by very small impurities of metal salts in the bases):

$$ROOH + B^- \rightarrow ROO^- + B\text{–}H \qquad (50^r)$$

Chain reaction:

$$ROO^- + ROOH \rightarrow RO^- + O_2 + ROH \qquad (51^r)$$

$$RO^- + ROOH \rightarrow ROH + ROO^- \qquad (52^r)$$

In secondary dialkyl peroxides, the C–H bond at the same atom as the peroxy group is attacked:

(53[r])

Bases have practically no effect on tertiary dialkylperoxides.

Reactions with Olefins. In the absence of epoxidation catalysts (e.g., Mo complexes) hydroperoxides predominantly react with olefins according to:

(54[r])

whereas peroxyacids mostly give epoxides very selectively in a nonradical reaction (Prilezhaev reaction; see Section 5.1)

(55[r])

Reactions with Ketones. Hydroperoxides readily add to ketones. The resulting perketals are labile and decompose readily, forming a variety of products:

(56[r])

Peroxyacids react with ketones with C–C bond cleavage to give esters or lactones (Baeyer–Villiger reaction).

(57[r])

Reactions with Aldehydes. Peroxy acids add to aldehydes more readily than to ketones, forming the corresponding aldehyde monoperesters. Cleavage of these compounds gives the corresponding acids. This cleavage is selectively catalyzed by Mn^{2+}/Mn^{3+} ions (see Section 4.4.2) In the oxidation of aldehydes to acids almost the entire acid is formed via this pathway:

(58r)

Reactions with Radicals. Radicals preferably attack C–H bonds at the same C-atoms that are already bearing other substituents like OOH or OH groups (see Table 10):

(59r)

Reactions of Alkoxy Radicals. The alkoxy radicals formed in the decomposition of hydroperoxides are very reactive (see Chap. 4.1). However, only primary alkoxy radicals appear to react predominantly by abstraction of hydrogen atoms to form alcohols. Secondary and, above all, tertiary alkoxy radicals react predominantly by C–C cleavage to give aldehydes or ketones, together with small amounts of alcohols.

(60r)

(61r)

(62r)

The C–C cleavage reactions (Reactions 61r and 62r) are very important in autoxidation because the carbon chain degradation proceeds mostly by these mechanisms. However, in the following examples, abstraction of H atoms or addition is preferred to C–C cleavage:

(63r)

(64r)

In olefin oxidations, alkoxy radicals also add to C=C double bonds:

(65r)

Oxidation of Alcohols, Aldehydes, and Ketones. The oxidation of primary alcohols proceeds via intermediate aldehydes and acetals to give the corresponding acids and esters.

In the autoxidation of secondary alcohols ketones and H_2O_2 are formed:

(66r)

(67r)

H_2O_2 process from BASF

The oxidation of cyclohexanol gives cyclohexanone and H_2O_2, which are in equilibrium with the intermediate cyclohexylperoxyacetal:

(68r)

The ketones formed are further oxidized via the α-hydroperoxyketones:

(69r)

The addition of peroxy radicals and hydroperoxides to ketones has already been mentioned (Reactions 38r, 56r, and 57r).

Aldehydes form addition products with polar compounds in the liquid phase. In the addition product the C–H bond of the aldehyde group becomes strongly activated by two polar groups (see Section 4.1, and Table 10, where the activation of the C–H bond by one polar substituent is shown):

(70r)

(71r)

(72r)

(73r)

The acyl radicals formed initially can decompose forming an alkyl radical and CO if there is an oxygen deficiency (Reaction 72r) or can also recombine to give diketones (Reaction 73r: synthesis of diacetyl from acetaldehyde).

Carbon monoxide and carbon dioxide are formed in autoxidation almost exclusively by decomposition of acyl and acyloxy radicals (Reactions 72r and 45r).

The presence of CO in the reaction waste gas (at an order of magnitude of ≤ 0.1 vol %) is thus a sensitive indicator of oxygen deficiency in autoxidations.

Cooxidation is the simultaneous oxidation of several substances. The cooxidation of aldehydes and olefins to produce epoxides (and acids) is particularly well known:

(74r)

as is the cooxidation of *p*-xylene and paraldehyde or methyl ethyl ketone in acetic acid to give terephthalic acid and acetic acid (Toray, Olin-Matheson).

As is apparent from the preceding sections, practically every autoxidation becomes a cooxidation soon after initiation. Planned cooxidation has achieved great importance, e.g., for elucidating reaction mechanisms and determining the relative reactivity of homologous species.

4.4.2. Metal Catalysis in Homolytic Liquid-Phase Oxidation

Homolytic liquid-phase oxidation is influenced by many metal ions, but only metals that can occur in two valence states of approximately equal stability in the oxidation medium can act catalytically. These are above all Co^{2+}/Co^{3+} and

Mn^{2+}/Mn^{3+}. Ionic pairs such as Cu^{+}/Cu^{2+} and Fe^{2+}/Fe^{3+} are important only in special cases.

The catalytic activity of these metals is based on the acceleration of peroxide decomposition by lowering the activation energy:

Thermal activation ($E_a = 90 - 170$ kJ/mol):

$$ROOH + ROOH \longrightarrow ROO\bullet + H_2O + RO\bullet \qquad (23^r)$$

Metal catalysis ($E_a = 40 - 50$ kJ/mol):

$$ROOH + Co^{2+} \longrightarrow RO\bullet + Co^{3+} + OH^- \qquad (75^r)$$

$$ROOH + Co^{3+} \rightleftharpoons ROO\bullet + Co^{2+} + H^+ \qquad (76^r)$$

$$2\ ROOH \xrightarrow{(Co^{2+}/Co^{3+})} ROO\bullet + H_2O + RO\bullet \qquad (77^r) = (75^r) + (76^r)$$

Because alkyl hydroperoxides are strong oxidants, Reaction (76^r) is only important in the decomposition of pure hydroperoxides, i.e., during the initiation step. After initiation the metal ions in the higher valency state are preferably reduced by aldehydes, because aldehydes are strongly reducing compounds:

(78^r)

(79^r)

Cobalt is the most important catalyst for homolytic oxidations, because only Co^{3+} has an oxidation potential high enough to oxidize hydrocarbons to cation radicals which decompose instantaneously to give radicals and protons:

$$RH + Co^{3+} \rightarrow RH\cdot^{+} + Co^{2+} \qquad (80^r)$$

$$RH\cdot^{+} \rightarrow R\cdot + H^{+} \qquad (81^r)$$

Therefore, in the decomposition of hydroperoxides (Reaction 75^r) two active species ($RO\cdot$ and Co^{3+}) are formed only with cobalt as catalyst. Formation of these species results in branching of the reaction chain and an increase in the reaction rate.

Mn^{2+}/Mn^{3+} catalyze the decomposition of hydroperoxides in the same way as cobalt ions. But since Mn^{3+} is unable to oxidize hydrocarbons, its catalytic activity is considerably lower than that of Co^{3+}. However, manganese is of great importance in the homolytic oxidation of hydrocarbons to acids, because it selectively catalyzes the splitting of the addition product of peracids and aldehydes (the aldehyde monoperester) into two molecules of acid (see Reaction 58^r).

Prior to decomposition, the hydroperoxides have to form complex compounds with the metal ions. Therefore, the rates of these redox reactions depend strongly on the medium. In polar media, such as acetic acid, the redox reactions can take place via extremely fast ligand transfer.

In nonpolar media, such as hydrocarbons, only electron transfer is possible, which is orders of magnitude slower than ligand transfer but still considerably faster than thermal decomposition.

In the series: alkyl hydroperoxide $<$ alcohol $<$ water $\approx$ acid, the hydroperoxides are the weakest complexing agents. Therefore alcohols, but in particular water and acids, act as catalyst poisons by competing with the hydroperoxides for the metal ion complex sphere. If these compounds are present in appreciable amounts – that is the case in nearly every normal oxidation – $Co^{2+/3+}$ has to be added in fairly high concentrations, e.g., in polar media 0.05 – 1 wt % and in nonpolar media 1 – 500 ppm (ca. $10^{-4} - 10^{-5}$ mol/L).

Because water and acids act as catalyst poisons, water and acids formed during the reaction should be stripped off to as low concentrations as possible. Acids, which cannot be stripped off, will slow down the oxidation rate long before the hydrocarbon starting material is consumed. In the special case of oxidation of *p*-xylene to DMT, the acid intermediate is esterified in order to achieve conversion of the second methyl group as well (see below: Witten – Imhausen – Katzschmann process, now Hüls process).

Peroxy radicals are strong oxidants. Therefore they oxidize Co^{2+} according to:

$$ROO\cdot + Co^{2+} \rightleftharpoons ROO^{-}\ Co^{3+} \qquad (82^r)$$

In the oxidation of *p*-xylene to TPA the peroxy anion formed further reacts to form the corresponding aldehyde:

(83[r])

(AcO^- = acetate anion)

In nonpolar media the initiation of an oxidation by hydroperoxides can come to a halt if the concentration of the Co ions becomes greater than the hydroperoxide concentration (catalyst-inhibitor conversion). Because all hydroperoxide is tied up in the complex sphere of the Co ions, excessive Co^{2+} competes effectively with the substrate RH for the alkylperoxy radicals according to Reaction (82[r]) and hinders chain propagation by:

$$ROO\cdot + RH \longrightarrow ROOH + R\cdot \qquad (20^r)$$

In polar media such as acetic acid these phenomenon does not appear because sufficient complex ligands are available.

The decomposition of dialkyl peroxides is accelerated by Fe^{3+}, Cu^{+}, and complex compounds of Mo^{6+}, W^{6+}, V^{6+} and Ti^{4+} (see Section 5.1). $Co^{2+/3+}$ and $Mn^{2+/3+}$ decompose dialkyl peroxides only under conditions which are not relevant to autoxidation.

Peroxyacids are decomposed analogously to alkyl hydroperoxides:

(84[r])

Because peroxyacids are stronger oxidizing agents and much weaker reducing agents than hydroperoxides, reduction of Co^{3+} ions only occurs with aldehydes according to Reactions (78[r] and 79[r]).

Effect of the Catalyst and the Medium. The metal ions have a major influence on the course of the reaction, as the following examples show.

Oxidation of cyclohexane:

Without catalyst	1	:	2
With Co or Mn catalyst	3	:	2

(85[r])

The oxidation of acetaldehyde can be controlled to give considerable amounts of diacetyl or acetic anhydride besides acetic acid, depending on the nature and concentration of the catalyst. In both cases the production of CO, CO_2, and CH_4 is enhanced, too.

Oxidation in acetic acid with catalytic quantities of Mn gives acetic acid according to Reactions (58[r]), (70[r]), (71[r]), (78[r]), and (79[r]).

Addition of catalytic quantities of copper acetate to the $Co^{2+/3+}$ catalyst leads to formation of acetic anhydride in addition to acetic acid:

(86[r])

(87[r])

The Cu cations seem to stabilize the acyl cations and anions and the peroxyacyl radicals.

Oxidation in the presence of large quantities of manganese(III) acetate gives diacetyl, acetic acid (and CO, CO_2, CH_4):

Oxidation of p-xylene: pure *p*-xylene is mainly oxidized to *p*-methylbenzoic acid in the presence of 100 – 200 ppm Co and up to 100 ppm Mn acetate in a normal radical chain reaction at 140 – 180 °C and 10 bar. The greater part of the second methyl group can only be oxidized after esterification of the *p*-methylbenzoic acid (hindrance by the acid formed) (Witten – Imhausen – Katzschmann process, now Hüls process):

Single-stage oxidation of both methyl groups succeeds in acetic acid in the presence of 500 – 1000 ppm Co and Mn acetate and either a peroxyacid-forming cooxidizing agent such as paraldehyde or acetaldehyde (Toray, Eastman-Kodak), or with Br ions as radical sources (Mid-Century/Amoco).

Whereas the peroxyacid formed in the Toray or Eastman-Kodak process overcomes the low oxidizability of the second methyl group, which is due to the carboxyl group, in the Mid-Century/Amoco process Co^{3+} and the Br • radical formed act as abstractors for protons or H atoms, respectively:

The intermediate 4-carboxybenzaldehyde is rapidly oxidized further to give the acid. Nevertheless, the removal of residual aldehyde is the major problem in the purification of the crude terephthalic acid (TPA), which crystallizes out rapidly due to its insolubility in the reaction medium and occludes small amounts of aldehyde, which are thus protected from further oxidation. Amoco solved this problem by hydrogenating the carboxybenzaldehyde with palladium as catalyst.

In the cooxidation process, only ca. 0.2 t acetic acid per tonne TPA are formed although the cooxidant agent must be present in at least a stoichiometric ratio.

In the Mid-Century/Amoco process 0.05 t acetic acid are consumed per tonne TPA.

One reason for the low yield and high loss of acetic acid is its metal-ion-catalyzed decarboxylation (Reaction 93r).

The decarboxylating activities of some metal ions are listed in Table 11. The reaction (93r) is fast above 140 °C.

Table 11. Relative activity of various metal ions in the decarboxylation of carboxylic acids

Metal ion	Relative activity
Ce^{4+}	1
Ag^{2+}	2
Pb^{4+}	20
Co^{3+}	100
Mn^{3+}	500

4.4.3. Inhibitors of Homolytic Liquid-Phase Oxidation

Inhibitors are substances that hinder the formation of the active intermediates (radicals, hydroperoxides, catalysts) or lower their concentration by complexing, decomposing, or trapping them.

The effect of phenols and aromatic amines is particularly well known. Because of their weak O–H and N–H bonds, they readily transfer H atoms to radicals. The resulting phenoxy or arylamino radicals are extremely unreactive due to resonance stabilization and, in the case of 2,6-disubstituted phenols, because of the strong steric hindrance. The radical chain reaction is thus interrupted, as shown in Reaction (94^r):

(94^r)

X = Alkyl; not alkoxy

An inhibitor molecule can thus capture two radicals. The relative efficiency of the inhibitors depends strongly on the substituents (Table 12).

Table 12. Relative inhibitor effect of trialkylphenols∗ on the oxidation of crude oil , p. 50[3]

R^1	R^2	R^3	Relative inhibitor effect ∗∗
H	H	Me	10
tert-Bu	*tert*-Bu	*tert*-Bu	36
Me	Me	*tert*-Bu	46
tert-Bu	*tert*-Bu	*sec*-Bu	80
tert-Bu	*tert*-Bu	Me	100
Me	Me	Me	118
tert-Bu	*tert*-Bu	Ethyl	125
tert-Bu	*tert*-Bu	*n*-Bu	140
Me	*tert*-Bu	Me	170

∗ 
∗∗ 2,6-Di-*tert*-butyl-4-methylphenol = 100

Whereas phenols and amines mainly capture radicals, organic sulfides and thiols usually react with hydroperoxides as follows:

(95^r)

For this reason mixtures of organic sulfides and phenols or amines have a stronger inhibiting effect than the individual components (inhibitor synergism).

Disalicylidine-1,2-propylenediamine

The inhibiting effect of an excessively high metal concentration has already been mentioned (see Section 4.4.2). Compounds that form metal complexes can also act as inhibitors if the number of donor centers corresponds to the coordination number of the metal. For example, disalicylidene-1,2-propylenediamine is added to gasoline in concentrations of 10^{-8} mol/L because it forms stable complexes with metals,

thus preventing them from catalyzing autoxidation.

It is noteworthy that phosphates, especially di- and triphosphates, appear to inhibit radical chain oxidation. They are not only the most effective fire-extinguishing powders (in the form of ammonium hydrogen phosphate), and, as pyrophosphate ($P_2O_7^{2-}$), a component of many heterogeneous gas-phase oxidation catalysts, but are also components of important building blocks of all living cells in the nucleotides and nucleic acids. In what way they interfere with the radical chain oxidation has apparently not yet been investigated.

For an introduction to autoxidation and the effect of inhibitors and stabilizers, in particular with reference to the protection of polymers from oxidative aging, see [3].

4.4.4. Special Cases of Homolytic Oxidation

Boric-Acid-Modified Alkane Oxidation (→ Alcohols, Aliphatic, Chap. 2.3.6.). The oxidation of hydrocarbons in the presence of suspended metaboric acid, known since 1928, appears to be a borderline case between homolytic and heterolytic oxidation. Secondary alcohols are preferably formed with unchanged carbon frameworks (selectivity > 80 %), together with ketones and diols. In the presence of olefins, epoxides are also formed in considerable yields.

The way of action of the boric acid is not clear yet. Until the 1970s it was believed that boric acid reacts only with the alcohol to form boric ester, which are very resistant to further oxidation. Later on epoxides were found, that are formed during the oxidation of olefins in the presence of boric acid. This led to the assumption that the boric acid already catalyzes the decomposition of the hydroperoxides. But, because in the oxidation of paraffins the ratio of secondary alcohols to ketones is very high (nearly no Russell reaction), it seems very likely that the boric acid reacts directly with the peroxy radicals to the corresponding boric esters and hydroperoxy radicals.

After oxidation, the alcohols must be liberated from the boric esters by hydrolysis. Only one OH group of the boric acid reacts with the alcohol to give the ester.

In Reactions (97r) and (98r) the protons of the boric acid depicted in parentheses do not behave like normal protons. They do not take part in esterification.

Alkyl aromatics cannot be oxidized in this way because boric acid also catalyzes the Hock cleavage to give phenols, which inhibit further oxidation shortly after initiation.

Paraffin Sulfonation (→ Surfactants, Chap. 6.2.3.). A further special case is the paraffin oxidation process in the presence of SO_2. Of several variations, two are carried out industrially.

Sulfochlorination (Reed Process). Sulfur dioxide and chlorine are introduced into the paraffin at 25 – 35 °C in the presence of UV radiation. The reaction proceeds by a radical chain mechanism with alkylsulfonyl chloride (i.e., chlorosulfonic acid) as the final product.

The kinetic chain length is 4000 – 5000. The conversion is limited to 30 % to minimize further oxidation to di- and polysulfonic acids.

Sulfoxidation (Light – Water Process). If SO_2 and O_2 (in a molar ratio of 2: 1 to 10: 1) are passed through an *n*-alkane in the presence of UV radiation at 20 – 40 °C, alkyl persulfonic acid is initially formed in a radical chain reaction. In pure paraffin, the persulfonic acid reacts further to give dark colored products. If water is added to the alkane, the reaction is slower and for each mole alkyl sulfonic acid an equivalent quantity of sulfuric acid is formed. However, the product remains colorless because the water extracts the alkylpersulfonic acid and catalyzes its reaction with SO_2 to give alkylsulfonic acid and sulfuric acid. The alkane conversion is limited to ca. 1 % to keep the undesired polysulfonation low.

Initiation

(99r)

Chain propagation

(100r)

Decomposition of peracid

Alkane sulfonic acid
(R = C_{10} - C_{15})

(101r)

Remarkably, SO_2 adds faster to the alkyl radical than O_2. Excess of SO_2 is therefore important. The reactivity of the alkylpersulfonyl radical formed by subsequent addition of oxygen is similar to that of the alkylperoxy radical. The sulfonic acid group is thus situated predominantly at carbon atoms in the middle of the chain.

Aromatics, olefins, and branched-chain paraffins inhibit the reaction.

4.4.5. Process Technology of Homolytic Liquid-Phase Oxidation

The various starting materials (liquefied petroleum gas, low-boiling aldehydes to high-boiling, long-chain paraffins, alkylhydroanthraquinone etc.) and the widely differing products (from H_2O_2 to terephthalic acid) also require differing conditions (temperature, pressure, solvents, reactor material). Some general rules may be given, which are valid for most radical chain oxidations.

Reaction Parameters, Reactor Geometry, Operation. The aim of industrial reactions is to produce as much product as possible per unit time and reactor volume. Because the mass flow of the educts, reaction temperature, and catalyst concentration can be chosen freely within limits, these parameters are normally maximized to give high throughput and production numbers. Consequently, O_2 transport from the gas to the liquid phase becomes the rate-determining step, often at the expense of lower product selectivity. This is even worsened by the fact that for safety reasons the O_2 content of the off-gas is usually kept near to 0 vol %, resulting in O_2 deficiency in the upper part of the bubble column.

Table 13. Solubility of oxygen in organic compounds at 1 bar [38, p. 1 ff]

Solvent	T, °C	O_2 concentration, 10^{-3} mol/L	α*
Benzene	20	9.1	0.204

Benzaldehyde	5	4**	0.090
Decanal	5	4	0.090

* α=cm^3 O_2 (STP) cm^{-3} bar^{-1}.
** The determination of O_2 solubility requires a long time for equilibrium to be reached. Hence, the values for readily oxidizable substances such as aldehydes are probably too low.

To test whether an oxidation is controlled by O_2 transport, it is sufficient to increase the O_2 pressure and to see if the reaction rate subsequently rises. According to Equation (5) if there is an adequate O_2 supply the reaction rate is independent of the O_2 concentration and thus of the O_2 transport. The solubility of O_2 in organic solvents is only ca. 10^{-2} mol/L (see Table 13).

Apart from the O_2 partial pressure, the rate of O_2 transport from the gas to the liquid phase

depends only on the area of the phase boundary surface, i.e., the bubble size. Therefore, the gas must be divided into the smallest bubbles possible on entry into the reactor and these must be prevented from coalescing into larger bubbles while they rise up the liquid column.

If turbulence is too severe and there is consequent coalescence, large gas bubbles are formed and the oxygen cannot pass into the liquid phase quickly enough. Oxygen then appears in the waste gas, although the oxidation suffers from an O_2 deficiency.

The gas velocity based on the reactor cross-section should thus clearly lie below 0.02 m/s. At higher velocities turbulence arises in the bubble column which promotes coalescence of the gas bubbles.

The height of the liquid phase in the reactor above the air inlet must be adapted to the rate of O_2 take-up. It can be determined in pilot experiments (see below). Generally 4 – 6 m should be sufficient. The volume required for the necessary throughput should be obtained by increasing the cross-section of the reactor (tanks instead of columns). In industry, for historical reasons, most oxidation reactors in operation are much higher (up to 30 m and more with liquid heights of 8 to more than 20 m). The reaction pressure should be chosen in a range where boiling of liquids is avoided because the vapor formed would enlarge the gas bubbles and lower the O_2 concentration in the bubbles, thus hinder oxygen transport.

Reactors for radical chain reactions must have the smallest possible surface to volume ratio because of the undesired radical recombination that always occurs at the walls. Apart from necessary built-in devices, like sieve plates for gas redispersion and cooling tubes, packings and devices with large surface areas should not be used in the reaction section. However, in the gas space above the bubble column packings with large surface areas are recommended to suppress gas explosions.

Oxidation can be operated as a batch or continuous process. In a continuous process the residence time spectrum is broadened, as part of the fresh starting material is carried straight out again because of the generally strong back-mixing. Accordingly, part of the product remains longer in the reactor and is overoxidized. The selectivity is thus lower than in batch processes. For this reason many large-scale oxidations are still performed batchwise even today. The selectivity in continuous oxidations can generally be improved by using baffles (sieve plates, etc.), which convert the reactor into a bubble column cascade and lower back-mixing.

Figure 9. Corrosion resistance of various materials
The effective corrosion resistance of each material in an acid environment is that portion of the chart below each bar (with kind permission of Gulf Publishing Comp., taken from *Hydrocarbon Processing,* June 1979, p. 214).

Reactor Materials; Corrosion. The choice of reactor materials is determined by the reaction medium and conditions (temperature, pressure, etc.). Most base metals and alloys are only protected from chemical attack by a dense, tightly adhering layer of oxide (passivation). These materials (Al alloys, Ti, stainless steel) are generally stable towards oxidizing media, but are readily attacked by reducing media (see Fig. 9).

Because many heavy metal ions also have a catalytic effect, aluminum and its alloys are recommended for the oxidation part under moderate conditions of temperature and pressure. For higher temperatures and pressures, stainless steel is recommended. Stainless steel is, however, rapidly attacked by halide ions even in an oxidizing medium. Therefore, for example, for the Mid-Century process reactors coated with titanium or Hastelloy C must be used.

Copper can inhibit many oxidations even in extremely low concentrations. Because copper is contained in fine dispersions in some lubricating agents and slip additives, particular attention

should be paid to such substances in the case of initiation problems.

In all parts of a plant in which O_2 is absent, i.e., where reducing conditions prevail, special care must be taken to ensure that the reactor material and the temperature are mutually compatible. For example Material no. 4571 (V4A E; US specification: SS 316 Ti) is rapidly attacked by acetic acid in the absence of O_2 above 140 °C. In the presence of O_2 it is stable towards the acid up to and above 160 °C.

The corrosivity of organic materials increases with the acidity, reducing capacity, and capacity for complex formation. Besides formic acid, hydroxyacids such as lactic and glycolic acids are the most corrosive.

Oxidation on Laboratory and Pilot Plant Scale. An apparatus is shown in Figure 10 which is suitable for most laboratory scale homolytic oxidations. Some aspects to which attention should be paid are as follows:

Figure 10. Laboratory apparatus for liquid-phase oxidation of high-boiling compounds
a) Thermostats; b) Gas metering; c) Cold traps; d) Off-gas cooler; e) Water separator; f) Gas sampling; g) O_2 analysis; h) CO/CO_2 analysis; i) Gasmeter

Reactor dimensions:

	Laboratory	Pilot plant
Diameter, cm	> 5	> 30
Height, cm	> 30	up to 800

In larger pilot reactors back-mixing can be limited by the incorporation of, for example, sieve plates.

Reactor Material. In the laboratory, glass should be used if possible (so that the reaction can be observed). With metals, oxygen-free zones should be avoided because of possible corrosion, possibly by O_2 purging.

Reaction temperature is the most important parameter; constant temperature can best be achieved by using two heating circuits: one at the desired reaction temperature for heating the jacket and one for inner cooling which is kept 10 – 50 °C below the reaction temperature.

The size and shape of the *cooling circuit* depend on the reaction and dimensions of the reactor. Cooling tubes should be arranged vertically and sufficiently far from one another and from the wall to minimize disturbances to the gas distribution.

Gas distribution is the second most important parameter. Tubes with small holes or frits made of glass, Teflon, or metal are the most suitable. For metal reactors, the frits should be tested periodically in glass vessels under conditions similar to those of the reaction.

Oxygen Content of the Off-gas. At 0 % oxygen content the experimental results are uncertain because the size of the O_2 deficiency zone is unknown. If higher O_2 contents are permitted in the off-gas, the necessary safety measures must be adhered to very precisely (see Section 4.6).

A water separator is important in the oxidation of nonpolar substances and is recommended for other substances if water is formed as a separate phase.

Gas Sampling. The O_2, CO, and CO_2 content in the off-gas should be continually monitored if possible; attention should be paid to volatile substances (e.g., H_2, CH_4, CH_3CHO). The gas sampling vessel should be purged with at least ten times the volume of the vessel to obtain correct values.

Course of a Liquid-Phase Homolytic Oxidation. Batch and continuous oxidation reac-

tions can be initiated as follows. The carefully cleaned reactor is charged with the starting material and the catalyst under nitrogen purging, the pressure is adjusted to the required value, and the mixture heated to the initiation temperature. Then air or O_2 is introduced and, if necessary, an initiator added. The start of the reaction can be detected by the decrease in the O_2 content of the off-gas and a rise in the reaction temperature. From this time onwards the O_2 supply is increased in such a way that the O_2 content in the off-gas does not exceed a critical limit, for instance 5 %. The acceleration of the reaction to maximum velocity usually occurs rapidly (within 10 to 30 min). The heat of reaction must be removed and the desired reaction temperature regulated. With proper layout, the temperature of the cooling medium and the control function of the valve in the cooling circuit can be adjusted on installation of the system such that the oscillations of the reaction temperature are maintained below 0.1 °C. For batch oxidations, the temperature of the cooling circuit must gradually approximate the reaction temperature towards the end of the reaction, to avoid excessive temperature fluctuations or breakdown of the oxidation process. In continuous oxidations, charging of starting material and removal of the product begin after the required conditions have been established.

Applicability of the Results from Laboratory and Pilot Plant to Full Plant Scale. Scale-up problems are mainly caused by the following factors:

1) The laboratory and pilot plant reactors often have too small a diameter relative to their height. Because the rising gas bubbles entrain liquid, a downward streaming in the rest of the liquid is always produced, predominantly at the wall of the reactor. The resulting turbulence leads to rapid coalescence of the gas bubbles in reactors that are too narrow. Thus the exchange area becomes much smaller and the reaction appears to be slower than it is.
2) The O_2 content of the off-gas is kept near 0 % (for further explanation, see above).

Results that are representative for full plant scale are only obtained with reactors which are of the same height as large-scale reactors and have a diameter such that the gas velocity remains well below 0.02 m/s (diameter 30 cm minimum).

4.5. Homolytic Gas-Phase Oxidation

Homolytic gas-phase oxidations are all combustion processes and gas explosions that take place in free gas space without heterogeneous catalysts. Examples include the combustion of heating oil and natural gas for the production of heat and energy and the rapid combustion of gasoline and diesel in internal combustion engines. Thus the homolytic gas-phase oxidation is one of the most important chemical reactions with respect to the amounts of materials consumed.

Mechanism. In principle up to 250 °C homolytic gas-phase oxidations proceed by the same mechanism as liquid-phase oxidations (see Section 4.3).

However, whereas oxygen transport from the gas to the liquid phase generally limits the rate of the overall reaction in a controlled liquid-phase oxidation, no comparable restriction exists in the gas phase. In the liquid phase the reaction temperature can be held constant at low levels by simple means. The rise in temperature is inversely proportional to the mass of the reaction mixture, and the heat of reaction is quickly transported to the walls of the cooling tubes by convection of the liquid. For reactions in the homogeneous gas phase, the temperature difference for adequate heat removal must be much greater because of the small mass. If the reaction is not limited by the quantity of fuel or oxygen, and the reaction space is not kept very small and well cooled, temperatures of over 1000 °C can occur in gas-phase oxidations, whereby heat transfer to the surroundings occurs mostly by radiation.

Because the intermolecular interactions, in particular through hydrogen bond formation, are considerably weaker in the gas phase than in the liquid phase due to the greater intermolecular distances, in the absence of catalysts, hydroperoxide decomposition can only occur thermally. Because the activation energy for thermal hydroperoxide decomposition is high (see Section 4.4.2), gas-phase oxidations only proceed at the same rate as a comparable liquid-phase

Table 14. Limiting values for the inerting of flammable gases and vapors with N_2 or CO_2 at 20 °C and 1 bar [28]

Compound	Minimum volume ratio				Maximum O_2 concentration in the F+A+inert gas mixture for inerting with N_2 or CO_2

Benzene	21	13	0.79	0.45	11.2	13.9

* Values do not exist due to ready decomposition of ethylene oxide.

oxidation at considerably higher temperatures. However, because heat removal is poor, an initiated gas-phase oxidation accelerates considerably faster than a corresponding liquid-phase oxidation and can readily become a thermal explosion.

Up to ca. 250 °C, hydroperoxides predominate as the first neutral intermediates. Between ca. 300 and 450 °C, isomerization and decomposition of the peroxy radicals to give aldehydes and other fragments becomes faster than hydroperoxide formation. Thus above ca. 420 – 450 °C practically no more alkylhydroperoxides are formed, and aldehydes and alcohols together with olefins and H_2O_2 are the primary neutral intermediates.

The decomposition of peroxy radicals, usually with preceding isomerization, has a higher activation energy than the hydroperoxide decomposition. Therefore, in the transition range between 320 and 450 °C, the overall reaction rate of gas-phase oxidation decreases with increasing temperature (region of negative rate – temperature coefficients), and subsequently rises more sharply than before.

Catalysis and Inhibition. Gas-phase oxidations are catalyzed by radical-forming substances (halogens and their compounds, NO/NO_2, nitro compounds, volatile peroxides, phenols, and amines) and also by high-energy radiation and cracking or dehydrogenation catalysts on the reactor walls.

In the gas phase, radical-forming substances generally only act catalytically if they are added in very low concentrations. In higher concentrations (sometimes even in the ppm range), the radicals formed act as radical scavengers for the more reactive hydrocarbon radicals. The mechanism of action of halogen compounds as fire-extinguishing agents and as flameproofing agents in plastics, and that of tetraethyl lead – used as an antiknock agent in gasoline up to the 1980s – is based on this radical trapping.

Chain termination by recombination of smaller, and therefore highly energetic, active radicals (such as $H\cdot$, $OH\cdot$, $CH_3\cdot$) can occur in the gas phase only if a third collision partner absorbs the energy of recombination (bond energy) liberated. Apart from the very rare three-body collisions, this occurs mostly through collisions with surfaces. Thus gas-phase oxidations, like all radical reactions occurring in the gas phase (e.g., decomposition of acetylene or ethylene oxide), are sensitive towards an increase in surface area. This is the mechanism of action of packings as flame arrestors, powder fire extinguishers, and dusts to control firedamp in mining. Degenerate radical chain explosions that proceed via hydroperoxides (e.g., in hy-

drocarbon – oxygen mixtures) can be stopped if fire-extinguishing powder or other radical scavengers are added early enough. This is because that due to indirect chain branching, the pressure rise during the initiation period is so slow, that sufficient time remains for releasing the fire-extinguishing device. But after the initiation period temperature and pressure can rise very sharply, changing the slow oxidation in a thermal explosion. These types of thermal explosion can rapidly become detonations, especially in enclosed spaces such as pipelines.

Nondegenerate branched radical chain reactions (such as the H_2/O_2 reaction), on the other hand, accelerate so rapidly due to direct chain-branching that no time remains for extinguishing measures once the reaction has started (see Fig. 3). They can only be hindered by preventive measures such as filling empty spaces with packings or capillary bundles.

Syntheses of Intermediates by Homolytic Gas-Phase Oxidation. Because of the extreme conditions, only a few simple products are produced by oxidation in the homogeneous gas phase. These include:

1) Synthesis gas (or hydrogen) by combustion of hydrocarbons or coal with a substoichiometric amount of oxygen and in the pres-

ence of water (→ Gas Production, Chap. 3.2.; → Gas Production, Chap. 4.1.).
2) Carbon black (rubber filler and strengthener) by combustion of oil or natural gas with a substoichiometric amount of oxygen (see → Carbon, Chap. 6.4.).
3) Acetylene by partial combustion of hydrocarbons (→ Acetylene, Chap. 4.2.).
4) CO_2 by complete combustion of natural gas.

The degradation of hydrocarbons and chlorohydrocarbons in the atmosphere takes place by radical chain reactions.

4.6. Gas Explosions and Safety Data

Modern civilization depends to a great extent on the use of hydrocarbons. However, great dangers can arise from these hydrocarbons in the presence of O_2 (see Fig. 11). Consequently, an extensive body of safety data has been generated to keep these dangers within acceptable limits and make the handling of hydrocarbons less hazardous. Extensive literature, standards and regulations exist in all industrial countries [23] , [28–36].

Figure 11. Characteristic damage caused by an atmospheric shock wave reflected from an object as a function of the peak pressure [28, p. 60]

The various safety terms are explained in [28], which also gives the corresponding standards for France, Germany, Russia, the United Kingdom, and the United States.

Explosion Limits, Explosion Groups, Ignition Temperatures, Temperature Classes, Flash Points, and Hazard Classes. All hydrocarbon vapors, and also many other substances, form explosive gas mixtures with oxygen within certain concentration limits, and these mixtures can be made to ignite if a certain, usually quite small amount of energy (electrical sparks, hot surfaces, etc.) is supplied. The lower and upper limiting concentrations of combustible gas at which an explosion can no longer be set off are called the lower and upper explosion limits.

In [28, p. 65] the opposite and therefore incorrect definition of the explosion limits is given.

Figure 12 shows the explosion limits of propane in air as a function of the pressure of the gas mixture before ignition and the ignition energy. Whereas the upper explosion limit is extended significantly by increasing either the pressure or the ignition energy, the lower explosion limit is lowered only to a small extent.

Figure 12. Explosion limits of propane in air as a function of the pressure p prior to ignition and the ignition energy E in a 7-L vessel
Ex_l = lower explosion limit; Ex_u = upper explosion limit
Reproduced from [23] with permission of the publisher

Combustible dusts behave in a manner similar to vapors [29].

In enclosed spaces (tanks, silos) the O_2 concentration can be lowered by dilution with inert gases (e.g., N_2, CO_2) to such an extent that an explosion can no longer be set off (see Table 14).

Above a certain temperature, the mixture ignites without an external ignition source due to autoxidation. This ignition temperature decreases with increasing chain length (see Table 15). It also decreases, in particular in the case of hydrocarbons, the longer the gas mixture has been kept at an elevated temperature below the ignition temperature (see Section 4.5). In pure oxygen the ignition temperatures can be up to 300 °C lower than in air. Like the explosion limits, the ignition temperatures are not substance-dependent constants but depend to a great extent on the measuring conditions. Table 15 lists explosion limits and ignition temperatures for some compounds in air at atmospheric pressure and 20 °C.

For safe handling of hydrocarbons being processed or stored in a plant the surfaces of hot apparatus, tubing, machines, etc. must be so well insulated that no danger of ignition can arise. For this reason combustible substances are classified according to ignition temperature into temperature classes T1 to T6 (see Table 16).

Table 16. Criteria for temperature classes [32]

Ignition temperature of flammable material, °C	Temperature class	Maximum surface temperature, °C	Former ignition class
>450	T1	450	G1
>300	T2	300	G2
>200	T3	200	G3
>135	T4	135	G4
>100	T5	100	G5
> 85	T6	85	

Also, areas where there is a danger of explosion are classified into areas according to the probability of the occurrence of explosive gas mixtures [28]:

Zone 0	Areas in which an explosive atmosphere is always present or present for an extended period of time.
Zone 1	Areas in which an explosive atmosphere is occasionally present.
Zone 2	Areas in which an explosive atmosphere is rarely present or present for only a short time.

Whereas hydrogen is diluted very quickly in air because of its low density and high rate of diffusion, hydrocarbons from propane onwards sink to the ground because of their relatively high density and low rate of diffusion. It has been shown experimentally that 10 m^3 of liquid propane evaporated within 10 min and distributed itself in a layer of 0.7 m thickness over an area of 700 m diameter. In addition the lower explosion limit of hydrogen is 4 vol %, while that of hydrocarbons lies between 1 and 2 vol %. Hydrocarbons are at least as dangerous as hydrogen.

Explosions cannot occur in spaces occupied by packing material. Explosions which have already started are quenched in vessels or pipes filled with Raschig rings, tube bundles, or similar packing materials (explosion barriers). The critical diameter of the capillary tubes at which no flame can be propagated is defined as the quenching distance. The quenching distance depends above all on the combustible gas, but also on the material, temperature, and mass of the explosion barrier. Capillaries and bead fillings are more effective flame barriers than parallel plates (see Table 17).

Table 17. Quenching distances of various flame barriers, [23, p. 58]

Fuel	Flame barrier		
	Parallel plate w_{max}, mm	Capillary, d_{max}, mm	Bead filling $d*_{max}$, mm
H_2	0.3	1	2
CH_4	1.3	4	7
C_3H_8	0.9	3	6

∗ Bead diameter.

Closely associated with the quenching distance is the maximum experimental safe gap (MESG), which principally applies to electrical equipment in surroundings where there is a danger of explosions. The safe gap is defined as that through which an ignition occurring inside the equipment is just unable to penetrate to the outside.

Substances are divided into three explosion groups corresponding to their hazard and assigned particular MESG values (see Table 18). The MESG is smaller than the quenching distance because, unlike the explosion barrier, the gap has a depth of only 25 mm.

Table 18. Classification of explosion groups according to maximum experimental safe gap (MESG) and minimum ignition current ratio (MIC) [32]

Classification	Condition	Example
II A	0.9 mm < MESG 0.8 < MIC	propane
II B	0.5 mm ≤ MESG ≤ 0.9 mm 0.45 ≤ MIC ≤ 0.8	ethylene
II C	MESG ≤ 0.5 mm MIC ≤ 0.45	H_2, C_2H_2, CS_2

The vapor pressure of liquids increases with temperature. The temperature at which the vapor pressure of organic liquids exceeds the lower explosion limit so that the vapor/air mixture above the liquid can be ignited, is defined as the flash point. Because dangers can arise, particularly from low-boiling substances, they have been divided into hazard classes according to flash point (Table 19). Because of the complexity and great number of regulations, the hazard classes according to the UN Recommendation which have arisen from the IATA and RID regulations are becoming increasingly important.

Self-Ignition of Solids, Fires from Liquids. Similar to gases, heat removal from solids is poor. In particular, with solids having large surface areas (coal dust, flour, hay, straw, paper waste, wood shavings etc.) oxidation can result in a significant temperature rise, whereby ignition occurs (see Table 20). The ignited solid only glows (reaction between O_2 and solids). Flames are formed by gas-phase oxidation of the gases and vapors formed by cracking and evaporation of the volatile compounds.

In the case of liquids it is also only the vapors formed which burn. For this the liquids must be heated to temperatures above the combustion point. At the flash point only the gas mixture above the liquid burns and the flame is then extinguished; however, when the combustion point is reached so much liquid evaporates that the gas mixture continues to burn. The combustion point is usually a few degrees above the flash point. Halogenated hydrocarbons, for which the combustion point can be up to 100 °C above the flash point, are an exception. This striking behavior and the suitability of halogenated hydrocarbons to be used as fire extinguishers are due to the same cause: These hydrocarbons form too many radicals. Therefore, at low temperatures, the proportion of chain termination reactions is too high.

Particularly critical situations can arise from fires involving containers of low-boiling liquids, if the container is heated. This can lead to sudden evaporation of a large quantity of liquid and a subsequent explosion. This process is known as BLEVE (burning liquid evaporating vapor explosion). A decision on the particular procedure can only be taken on the spot. But in all cases where the liquid can neither be pumped off nor quenched by dilution with water, a BLEVE should be hindered by intensive cooling of the container. The liquid which could otherwise not be disposed of should, however, be allowed to burn away, since clouds of gas forming after complete quenching by subsequently evaporating liquid could ignite at places which were still hot.

5. Heterolytic Oxidation

Both liquid- and gas-phase heterolytic oxidations have long been known and are used both in the laboratory and in industry.

For example, the oxidation of naphthalene to phthalic anhydride was carried out by BASF with sulfuric acid and $K_2Cr_2O_7$ since 1872, and since 1896 by the Sapper process with sulfuric acid and mercury as the catalyst. From 1916 this process was replaced by air oxidation on V_2O_5 catalysts.

Oxidations with HNO_3, SO_3/H_2SO_4, peroxomonosulfuric acid, MnO_2, KIO_4, etc., still play a role in industry today [17–20].

A more systematic investigation and determination of these reactions began in the 1960s, principally as a result of two developments:

1) The oxidation of ethylene to acetaldehyde with $PdCl_2$, developed by Wacker [39] and Hoechst.
2) Molybdenum-catalyzed epoxidation of propene with *tert*-butyl hydroperoxide, introduced by Halcon and Arco, and their joint venture, Oxirane.

Oxidation in the presence of heterogeneous catalysts is still based almost entirely on empirical principles (both in the liquid and gas phases). It profits considerably from developments in homogeneous liquid-phase oxidation

Table 19. Flash point limits of various transportation and storage regulations [28]

Regulation	Applies to	Class	Flash point limit, °C	Notes
VbF	storage	A I A II A III	< 21 21 – 55 55 – 100	incompletely miscible with water
		B	< 21	completely miscible with water

Zinc	10 – 15	90	4.9	430

∗ Temperature of the surface on which the dust lies. It decreases with increasing thickness of the dust layer. The maximum permissible surface temperature must be ca. 100 °C lower than the smoldering temperature.

since the course of reactions on solid surfaces cannot yet be directly investigated. It may be assumed, however, that many reactions on heterogeneous catalysts proceed in the same or at least similar ways with corresponding catalysts in the homogeneous liquid phase.

Depending on the substrate, oxidizing agent, type of catalyst, participating complexing agents, reaction medium, temperature, and the other reaction conditions, heterolytic oxidations proceed by various mechanisms. From the combination of different substrates with the different catalysts, oxygen donors, and reaction media, there is an extraordinarily large number of possible reactions. For this reason only a short overview can be given here, based on [16]. Further reviews can be found in [4], [12], [18–21].

5.1. Heterolytic Oxidation in the Liquid Phase

In heterolytic oxidations in the liquid phase other oxygen donors are frequently used instead of molecular oxygen. Some of these are listed in Table 21, together with the byproducts formed from them.

Table 21. Oxygen donors, [16, p. 5]

Donor	Active oxygen, %	Byproduct
H_2O_2	47.0	H_2O
tert-BuO_2H	17.8	*tert*-BuOH
NaClO	21.6	NaCl
$NaClO_2$	35.6	NaCl
NaBrO	13.4	NaBr
$C_5H_{11}NO_2$ [a]	13.7	$C_5H_{11}NO$
$KHSO_5$	10.5	$KHSO_4$
$NaIO_4$	29.9 [b]	NaI

[a] *N*-Methylmorpholine-*N*-oxide.
[b] Assuming all four O atoms are utilized.

Example 1: Uncatalyzed Epoxidation of Olefins by Peroxyacids (Prilezhaev Reaction). Due to the polarization of the neighboring C=O bond, the hydroperoxy group of peroxyacids can epoxidize C=C double bonds. Alkyl hydroperoxides are less electrophilic and require a catalyst (see Example 3 b)

(102[i])

Example 2: Stoichiometric Oxidation with Metal Oxides. Oxides such as SeO_2, CrO_2Cl_2, MnO_4^-, OsO_4, etc. have long been used as oxidizing agents for organic substrates. The following mechanism is assumed for the oxidation of propene by SeO_2:

(103[i])

(104[i])

(105[i])

In the presence of *tert*-butyl hydroperoxide (TBHP) and small quantities of SeO_2 the reaction proceeds catalytically (see also Example 3).

The active oxidizing agent is an oxometal species in the case of metal ions that are strong oxidizing agents in their highest oxidation state (e.g., Se^{4+}, Cr^{6+}, V^{5+}, Ce^{4+}, Ru^{8+}), while weakly oxidizing metal ions (e.g., Mo^{6+}, Zr^{4+}, Ti^{4+}) react as peroxometal species. V^{5+} can react by both mechanisms.

It should be noticed that metal ions reacting via "oxometal" mechanism are reduced by the substrate and reoxidized by the active oxidizing agent during one cycle, whereas the metal ions in the "peroxometal" complexes do not change their oxidation state but add the active oxygen donor to their complex sphere. In this way, primary alcohols can be oxidized (with Zr complexes) to aldehydes, secondary alcohols to ketones, and olefins to epoxides or glycols (see Example 3).

Example 3: Transition Metal Catalyzed Oxidation of Olefins.

a) Some transition metal oxides form inorganic peroxoacids with H_2O_2, analogous to the reactions shown in the above scheme. These inorganic peroxoacids, known as Milas reagents, oxidize olefins to epoxides. The epoxide formed is hydrolyzed in water (H_2O_2 is usually added as a 30 % aqueous solution):

(106[i])

(107[i])

The best known Milas reagent is OsO_4. However, it does not oxidize the olefins via the epoxides but via the osmates:

(108[i])

b) Halcon – Oxirane Process (→ Propylene Oxide). If olefins are treated with organic hydroperoxides in nonaqueous solvents in the presence of Milas reagents as catalysts, epoxides are formed in high yields:

(109[i])

Homogeneous catalysis: Mo^{6+}, W^{6+}, V^{5+}, Ti^{4+} (Arco)
Heterogeneous catalysis: Ti^{4+}/SiO_2 (Shell)

The following mechanism is assumed:

(110[i])

(111[i])

(112[i])

Whereas the alcohols formed from the hydroperoxides have a strongly inhibiting effect on the activity of vanadium, they inhibit the action of molybdenum only in high concentrations (e.g., when used as the solvent). For homogeneous catalysis the metals are added in the form of complexes that are readily soluble in organic materials in concentrations of 1 – 500 ppm. The reaction temperatures are between 80 and 120 °C. The problem of catalyst recycling was solved by Shell by rendering the catalyst heterogeneous.

The major problem of this process is that ca. 2 t *tert*-butanol (TBA) are formed per tonne of propylene oxide. Up to the 1980s Arco recycled the TBA by dehydration to isobutene and subsequent hydrogenation to isobutane. Today, isobutene is converted to methyl-*tert*-butyl ether (MTBE) for which a large market as gasoline additive has developed (→ Methyl-*Tert*-Butyl Ether).

Example 4: Palladium-Catalyzed Oxidation of Olefins. Wacker/Hoechst process (→ Acetaldehyde). SMIDT et al. [39] attempted to oxidize ethylene to ethylene oxide in the gas phase over Pd/C. In contrast to their expectations acetaldehyde was formed. In this way a reaction was rediscovered, which was known since 1894 and used analytically for a long time for determination of palladium. Since the catalysts rapidly became inactive in the gas phase because of formation of palladium aggregates, it was decided to carry out the reaction in the liquid phase (water). By combination with a redox system ($CuCl/CuCl_2$), a catalytic process for acetaldehyde synthesis was developed. Considerable corrosion problems arose due to the use of chloride ions in an acidic medium (pH 0.8 – 3) at 100 – 130 °C.

The reaction scheme is as follows:

$$C_2H_4 + PdCl_2 + H_2O \rightarrow CH_3CHO + Pd^0 + 2\,HCl \qquad (113^i)$$

$$Pd^0 + 2\,CuCl_2 \rightarrow PdCl_2 + Cu_2Cl_2 \qquad (114^i)$$

$$Cu_2Cl_2 + 2\,HCl + 1/2\,O_2 \rightarrow 2\,CuCl_2 + H_2O \qquad (115^i)$$

From experiments with C_2D_4 (very small isotope effect), D_2O ($k_H/k_D = 4.5$, no deuterium in the acetaldehyde), with varying H^+ and Cl^- concentrations (both ions inhibit the reaction), with various nucleophiles (acetic acid or ethanol instead of water as the solvent), and from the finding that *trans* OX substitution occurs in ethylene (OX thus comes directly from the solvent and not from the ligand sphere of the complex) it was concluded that the mechanism is as follows:

1) Substitution of a chloride ligand by ethylene, with formation of a π-complex, which is in equilibrium with the corresponding solvent complex by rapid ligand exchange:

(116^i)

(117^i)

2) Formation of the π-complex lowers the electron density on the ethylene ligand, rendering it susceptible to nucleophilic attack. The π-complex is in equilibrium with the σ-complex. The latter loses a Cl^- ion in a slow reaction and decomposes after hydride migration from C_1 to C_2 via the Pd, and two-electron transfer from C_1 to Pd, to give the final products. The Pd^0 is then reoxidized. Alternatives to this mechanism are discussed in [40], [41]

(118^i)

(119^i)

(120^i)

The two major drawbacks of the Wacker process – chlorinated byproducts and severe corrosion – can be overcome by using heteropolyacids (HPA) as the reoxidizing agents [42] instead of the $CuCl/CuCl_2$ system.

Higher olefins are oxidized to ketones. Yields of over 95 % are only obtained with HPA as the reoxidizing agent for palladium.

As shown above, vinyl acetate is formed in acetic acid (and in the presence of Na acetate). Isopropenyl acetate is formed from propene since Pd^{2+} is electrophilic and therefore reacts with the double bond in the manner shown in Reactions (116^i – 120^i) and (121^i). In contrast, Pd^0 abstracts the allylic H atom and gives a π-allyl complex. Thus propene is oxidized to allyl compounds on Pd^0 (on activated carbon or another carrier), whereby a cocatalyst (e.g., $CuCl_2$) is not required, unlike with Pd^{2+}. With water as solvent acrylic acid is formed (124^i).

(121^i)

(122^i)

(123^i)

(124^i)

Palladium(0) on activated carbon also catalyzes the oxidation of the methyl group of toluene under mild conditions:

(125^i)/ (126^i)

Further examples of the heterolytic oxidation of olefins are:

(127[i])

TBHP = *tert*-butyl hydroperoxide

Oxidative C=C cleavage:

(128[i])

(129[i])

Alcohols can be oxidized in a similar manner, as the following examples show:

Yield: 85 - 95 % (130[i])

Yield: 96 % (131[i])

Yield: 81 % (132[i])

acac = acetylacetonate
NAFK = Nafion R 511 perfluorinated ion-exchange resin

(133[i]), (134[i])

(135[i])

(136[i])

cat. : $Pb_{2.63}Ru_{1.37}O_{6.5}$ or $Bi_{2.39}Ru_{1.61}O_{7-y}$

Heteropolyacids (HPA) are gaining increasing importance because of their unique combination of properties:

1) Strong Brønsted acids
2) Multi-electron oxidizing agents
3) Solubility in water and oxygenated organic solvents (soluble oxides)
4) HPA anions are stable to oxidation and function as multi-electron ligands that can stabilize reactive, higher-valent oxometal species

For example, the oxidative cleavage of diols was achieved with H_2O_2 in *tert*-butanol in the presence of the cetylpyridinium salt of the heteropolyacid $H_3PW_{12}O_{40}$ as catalyst.

(137[i])

cat.: (cetylpyridinium)$_3$ $PW_{12}O_{40}$

To avoid the problems associated with catalyst recycling, Anic/Enichem has incorporated Ti^{4+} into a zeolite lattice and obtained titanium-silicalite (TS-1). TS-1 has the same elemental composition as the Shell Ti–SiO_2 catalyst, but a considerably wider range of applications. It is assumed that active, isolated titanyl species are responsible for the catalytic activity:

TS-1 (138[i])

With TS-1 as catalyst, the following reactions have, among others, been carried out with 30 % H_2O_2:

Selectivity: 96 % (139[i])

(140[i])

(141^i)

(142^i)

(143^i)

For hydrogen peroxide and the inorganic water-soluble oxygen donors, there is often a miscibility problem with the organic compound. This problem can be solved in many cases by using a two-phase aqueous – organic solvent system in conjunction with a phase transfer catalyst.

Process Technology of Heterolytic Liquid-Phase Oxidation. Because of the great number of possible reactions, general rules cannot be drawn up. In the cases where only liquids are reacted with each other, stirred tanks are suitable reactors for small batches. For continuous production, reactors with turbulent plug flow are generally the most suitable.

If a catalyst precursor is used a formation phase is necessary for initiation. After this formation phase, and with the use of preformed catalysts, the reaction proceeds immediately with its maximum possible rate.

The reactions are generally very selective. If the catalyst permits, they can be run until complete conversion of the starting material is reached.

5.2. Heterogeneously Catalyzed Gas-Phase Oxidation

The area of heterogeneously catalyzed gas phase oxidations is still largely empirical, with regard to the composition and preparation of the catalysts, and the control and influencing of the processes occurring on the catalyst surface during the reaction.

Considerable progress has been made in the investigation and characterization of surfaces. Surface analysis methods, such as Auger electron spectroscopy (AES), secondary ion mass spectroscopy (SIMS), and low energy electron diffraction (LEED), have been applied to catalysts. By using such techniques, considerable advances in the characterization of and the differentiation between good and poor catalysts have been made. This is important both for reproducible catalyst production and for the explanation of poisoning and aging processes.

Table 22. Types of catalyst for heterogeneous gas-phase oxidation

Catalyst	Reactions and examples
Noble metals(Pt, Pd, Ag)	
Pt(+ Rh,Au) gauze	NH_3 oxidation to NO/NO_2
	Andrussow process:
	$CH_4 + NH_3 + \frac{3}{2}\,O_2 \longrightarrow HCN + 3\,H_2O$
Pt(+ Rh)/TiO_2/carrier	off-gas combustion/purification
Pt(+ Bi,Au)/carrier	oxyacetylation, e.g.:
	ethylene ⟶ vinyl acetate
	propene ⟶ allyl acetate
Ag(+Cs)/carrier	ethylene oxide direct synthesis
Ag (pure)	oxidative alcohol dehydrogenation:
	methanol ⟶ formaldehyde
	ethanol ⟶ acetaldehyde
Cu - Fe catalysts	
$CuCl_2$(Alkali chloride)/carrier	Deacon process:
	$2\,HCl + \frac{1}{2}\,O_2 \longrightarrow Cl_2 + H_2O$
	Oxychlorination:
	$C_2H_4 + 2\,HCl + \frac{1}{2}\,O_2 \longrightarrow ClCH_2{-}CH_2Cl + H_2O$
Cu - Mn - Cr oxide	off-gas combustion/purification
Mg - Cr ferrite	oxidative dehydrogenation:
	butene ⟶ butadiene ∗
CuO - ZnO	oxidative decarbonylation:
	α-branched aldehydes ⟶ ketones ∗
	(e.g., isobutyraldehyde ⟶ acetone)
Cu_2O/carrier	propene ⟶ acrolein
Catalysts based on V_2O_5 + MoO_3	
V_2O_5(+ $K_2S_2O_7$)/carrier	Contact process: $SO_2 + \frac{1}{2}\,O_2 \longrightarrow SO_3$
V_2O_5(+ P_2O_5)/carrier	o-xylene ⟶ phthalic anhydride (→ phthalic acid)
V_2O_5(+ P_2O_5 + TiO_2)/carrier	butane/butene ⟶ maleic anhydride (→ maleic acid)
V_2O_5(+ MoO_3 + additives)/carrier	benzene ⟶ maleic anhydride (→ maleic acid)
V_2O_5(+ SnO_2 + additives)/carrier	ammonoxidation: alkyl aromatics ⟶ aromatic nitriles
MoO_3 - Bi_2O_3(+ various additives)	oxidative dehydrogenation:
	butene ⟶ butadiene
	ammonoxidation:
	propene ⟶ acrylonitrile
	propene ⟶ acrolein
MoO_3 - V_2O_5(+ various additives)	acrolein ⟶ acrylic acid
MoO_3 - Fe_2O_3	Formox process:
	methanol ⟶ formaldehyde

∗ Of minor industrial importance.

Most of these spectroscopic methods can, however, only be performed under high vacuum. Thus for all industrially interesting cat-

alysts one is still far away from investigating the processes occurring on the catalyst surface during the reaction. Nevertheless, a large number of observations and indirect methods of investigation, (e.g., sorption measurements, use of isotopically labeled compounds, alternating oxidation and reduction) in combination with the above-mentioned methods of physical analysis allows a rough picture to be built up of what happens on the surface of the catalyst.

As long as the processes on the surface of the catalyst are practically inaccessible to direct investigation, all proposed mechanisms can only be speculative.

For a summary of the literature up to 1972, see [43]; up to 1979, [12], [44], [45]; (see also → Heterogeneous Catalysis and Solid Catalysts).

5.2.1. Oxidation Catalysts

Table 22 lists the most important oxidation catalysts and the reactions catalyzed by them [46]. The catalysts are divided into three groups:

1) The *noble metals Pt and Ag* are the longest known catalysts. Their large-scale use as oxidation catalysts was limited for a long time to the combustion of ammonia (Pt/Rh, Ostwald process) and the synthesis of formaldehyde (Ag; BASF process). After World War II, the direct oxidation of ethylene to ethylene oxide on Ag, the oxydehydrogenation of ethanol on Ag to give acetaldehyde, and the Andrussow process for the synthesis of HCN on Pt catalysts became important. In the late 1960s, the combustion of off-gases on Pt/Rh and the acetoxylation of olefins on Pd were introduced.
2) In the 1940s *copper-based catalysts* became important for the oxidation of propene to acrolein. In the 1950s various mixed-oxide catalysts based on Fe/Cr oxide were developed for the oxidative dehydrogenation of butenes to give butadiene. In the 1960s the $CuCl_2$/carrier catalysts, known since 1868, achieved renewed industrial importance for the oxyhydrochlorination of ethylene/HCl mixtures to give dichloroethane (precursor for vinyl chloride).
3) After Pt and Ag, the *vanadium oxide catalysts* are the longest used industrial catalysts for oxidation processes; V_2O_5 was first used in the oxidation of SO_2 to SO_3, and later in the oxidation of naphthalene to phthalic anhydride, and benzene to maleic anhydride.

The discovery of the $Bi_2O_3 \cdot MoO_3$ catalysts by Sohio had a similarly revolutionary effect on the development of mixed-oxide catalysts for gas-phase oxidation, as the discovery of the palladium catalysts for ethylene oxidation on the development of the heterolytic liquid-phase oxidation.

Properties and Mechanism of Action of Heterogeneous Oxidation Catalysts. Most heterogeneously catalyzed oxidations probably proceed by heterolytic mechanisms. As shown in Section 5.1 these mechanisms differ, depending on the catalyst used.

Noble Metal Catalysts. A characteristic of noble metal catalysts is that reducing conditions must generally be used for selective oxidations; i.e., the hydrocarbon must be in excess and oxygen in deficiency. With excess oxygen the pure platinum metals in particular catalyze only complete combustion, which begins at 200 – 250 °C on active catalysts.

The most active catalysts for total combustion (off-gas purification) are based on Pt/Rh; they catalyze the complete oxidation of hydrocarbon compounds to CO_2 and H_2O at a stoichiometric O_2 availability.

For the acetoxylation of olefins over a Pd^0 catalyst, a mechanism was proposed in Reaction (123^i). It is assumed that this mechanism is also valid for the corresponding reactions in the gas phase. The palladium must be modified with Bi and Au, and sodium acetate must be continuously added to the starting material as a moderator, so that the reaction proceeds with the desired selectivity.

Oxidation of Ethylene to Ethylene Oxide on Silver Catalysts (see also → Ethylene Oxide, Chap. 4.1., → Ethylene Oxide, Chap. 4.2.). Up to now ethylene is the only olefin which can be selectively oxidized to the epoxide in the gas phase, and silver is the only catalyst on which the reaction proceeds with high selectivity.

Ethylene can be oxidized to ethylene oxide with an excess of oxygen on silver catalysts.

Because the selectivity decreases with increasing conversion, small ethylene conversions are used industrially. Because of the need to recycle the ethylene, pure oxygen is generally used. The oxygen concentration is determined by the lower explosion limit with respect to oxygen.

Figure 13 shows the development of the ethylene oxide selectivity. The first catalysts gave selectivities of ca. 50 %, which were gradually increased to 65 – 70 % by addition of a few ppm of a chlorohydrocarbon to the make-up gas to lower the activity, and by improvements in catalyst preparation. In the 1970s Shell raised the ethylene oxide selectivity from below 70 % to ca. 75 % by doping the catalyst with 100 – 500 mg/kg cesium [47]. Later, ethylene oxide selectivities of over 86 % were achieved by additional doping of the Ag/Cs/carrier catalysts with rhenium and sulfate ions.

Figure 13. Development of the selectivity in the oxidation of ethylene oxide since 1950
The selectivities attained in industrial plants lie in the shaded region

Although the oxidation of ethylene on silver has been known for 60 years and has been investigated intensively, there is no clarity over the mechanism either with regard to the activation of the oxygen or the ethylene. Two mechanisms are principally discussed for the oxygen activation (see also → Ethylene Oxide, Chap. 4.2.):

According to *mechanism 1* oxygen molecules adsorbed end-on on the silver surface at certain interstitial sites are believed to oxidize the ethylene diffusing to the site from the gas phase to give ethylene oxide selectively. The oxygen atom bound to the silver remains on the surface.

Ethylene oxide and carbon dioxide formation proceed in parallel in the industrially used temperature range and also over wide ranges of ethylene and oxygen concentration, and appear to be coupled with one another. Moreover, several studies showed that chemisorbed oxygen atoms only totally oxidize ethylene. It was therefore assumed that the chemisorbed oxygen atom remaining after transfer of one oxygen atom to ethylene, is subsequently removed by the other ethylene molecule with total oxidation. Subsequently, the cycle can start again.

In this mechanism one ethylene molecule can remove a maximum of six oxygen atoms from the interstitial sites at which ethylene oxide has previously been formed. Therefore, the ethylene oxide selectivity should not exceed the limit of $100 \times 6/7 = 85.7$ %.

In *mechanism 2* oxygen atoms adsorbed on the silver surface bring about both selective and total oxidation of ethylene. Is is assumed that promoter and moderator ions in the neighborhood of the active oxygen atom (e.g., Cs^+, Cl^-, and also O^{2-}) influence its electronegativity and thus determine whether it acts as a selective or total oxidant (lowering the electronegativity favors selective oxidation).

Given the available experimental evidence, arguments can be made in support of either mechanism [48].

If the ethylene oxide selectivity of more than 86 % reported in [49] is confirmed, the second part of mechanism 1 would be refuted.

There have been practically no investigations of the nature of the ethylene activation. It only seems certain that it does not react directly from the gas phase – as postulated in mechanism 1 – but is first adsorbed on the catalyst surface.

The reaction is zero, first, or fractional order, depending on the ethylene/oxygen ratio in the gas phase. Under industrial conditions (concentration < 9 % O_2, 30 – 40 % ethylene; per pass, 40 % of the O_2 and only ca. 10 % of the ethylene are converted), the reaction is zero order with respect to ethylene and first order with respect to oxygen.

The oxidative dehydrogenation of ethanol to give acetaldehyde (see → Acetaldehyde, Chap. 4.1.) on silver or copper catalysts has long been known and was formerly the method

of choice in the laboratory. Formaldehyde was also previously produced by this method, but is now mainly produced in the Formox process by oxidative dehydrogenation of methanol on iron molybdate catalysts (→ Formaldehyde, Chap. 4.2.).

In the Hüls process (originally developed by BASF), ethanol is mixed with air and passed over coarse-grained crystals of pure silver at 500 – 650 °C. There is only 50 – 70 % conversion of ethanol, but complete consumption of oxygen. The off-gas contains up to 11 % unoxidized hydrogen.

(144^{i})

(145^{i})

Copper Catalysts. Whereas the oxidation of HCl and the oxychlorination of ethane require temperatures over 400 °C, the oxychlorination of ethylene proceeds at ca. 230 °C. An electrophilic attack of the ethylene double bond on a copper hydroxy chloro complex with formation of an ethylene-chloronium complex and reduction of Cu^{2+} to Cu^{+} with subsequent transaddition of a second chloride ion to this chloronium complex is assumed. This is followed by reoxidation of the copper (Reaction 144^{i} + 145^{i}).

Mixed Oxide Catalysts. There are essentially two groups of mixed oxide catalysts:

1) Molybdenum-based catalysts that contain bismuth or vanadium and/or tungsten as the second main component and which are used, for instance for the oxidation of propene to acrolein and acrylic acid or to acrylonitrile, and for oxidative dehydrogenation of butene to give butadiene.
2) Catalysts based on vanadium, with, e.g., phosphate, sulfate, TiO_2, or MoO_3 as the second main component, are principally used for the oxidation of aromatics and butane/butene to give acid anhydrides (benzene or butane/butene to maleic anhydride, naphthalene or *o*-xylene to phthalic anhydride).

(146^{i})

While V_2O_5 and MoO_3 belong to the oxides which are themselves catalytically active, oxides such as Bi_2O_3, Sb_2O_3, SnO_2, and TiO_2 possess virtually no catalytic activity of their own. However, in combination with V_2O_5 and MoO_3 the catalytic activity and selectivity of the latter are greatly increased.

Hydrocarbon Activation on Mixed-Oxide Catalysts. Experiments with ^{14}C-labeled propene indicate that it is chemisorbed as a

π-allyl complex on the Mo/Bi catalysts with hydrogen abstraction. It is assumed that this π-complex reacts further with the metal oxo complex in a manner analogous to the reaction with SeO_2 with oxygen transfer and metal reduction (see Reactions 103^i to 105^i).

On a catalyst with the composition $Mo_{10}BiFeCo_4W_2K_{0.06}Si_{1.35}$ a selectivity for acrolein of 90 % was achieved at a propene conversion of 98 %. Only ca. 6 % of the acrolein was further oxidized to acrylic acid on this catalyst [total selectivity (acrolein + acrylic acid): 96 %].

The selective further oxidation of acrolein can be achieved on Mo – V catalysts (see → Acrylic Acid and Derivatives, Chap. 1.3.1.). Obviously the addition of vanadium leads to stronger adsorption and activation of the acrolein than on the Mo – Bi catalyst.

The oxidative dehydrogenation of butene to give butadiene proceeds similarly. On Mo – Bi catalysts the first step of the oxidation proceeds as with propene. Like acrolein, the butadiene formed is practically completely desorbed from the catalyst (selectivity > 90 %) and is not further oxidized. Two mechanisms can be discussed:

On vanadium-containing catalysts (see Table 22), however, the butadiene is rapidly oxidized further to maleic anhydride.

At the high temperatures necessary for the oxidation of butane (400 – 450 °C), vanadyl phosphate catalysts, $(VO)_2P_2O_7$, have proven particularly selective. The P : V ratio in the bulk catalyst particle is 1 : 1, corresponding to the stoichiometry, but on the catalyst surface it is 2 : 1. The phosphate apparently has two functions: it stabilizes the vanadium in high valence states by complexation and it inhibits homogeneous gas-phase oxidation of butane and its intermediates.

Methyl aromatics (toluene, xylene) and naphthalene are oxidized with the greatest selectivity on vanadium catalysts via the aldehydes to the acids or acid anhydrides. High yields are obtained only with those hydrocarbons that form moderately polar, readily desorbable, volatile products, such as *o*-xylene, from which phthalic anhydride is formed. *p*-Xylene initially affords terephthalic acid, which is too polar and is therefore hardly desorbed. The anhydride of terephthalic acid is oligomeric and therefore insufficiently volatile. For this reason *p*-xylene can be oxidized selectively in the gas phase only by ammoxidation to give terephthalonitrile. Normal air oxidation, in contrast, results predominantly in total oxidation.

Mixed oxide catalysts are only catalytically active and selective in their higher oxidation states. Unlike the noble metal catalysts they must be used in an excess of oxygen, i.e., in an oxidizing atmosphere.

It is generally assumed that the oxygen originates from the oxide lattice in selective oxidations on mixed oxide catalysts and that the metal ions are reduced and oxidized again alternately (redox mechanism of Mars and Van Krevelen). Up to now there are only vague ideas about the way in which atmospheric oxygen is activated and incorporated into the lattice.

Whereas reoxidation proceeds very rapidly on vanadium catalysts (the reaction temperature is mainly determined by the temperature necessary to activate the hydrocarbon), the reoxidation of the catalyst is the activity-determining process for molybdenum-based catalysts, which also determines the reaction temperature. This is demonstrated, for example, by the fact that for catalysts based on V_2O_5 the active mass can be applied as a thin layer on a carrier (egg-shell catalyst), while catalysts based on MoO_3 only exhibit sufficient activity as bulk catalysts.

The importance of the reoxidation rate in mixed oxide catalysts, is exemplified by the development of the Bi–Mo catalysts. When they were introduced by Sohio in the early

1960s, the temperature required for oxidation of propene was 400 – 450 °C, and the selectivity for acrolein, between 60 and 70 %. By the addition of metal ions such as Fe(II/III), Cu(II), Co(II) and Ni(II), which only catalyze one-electron transfers, the reaction temperature could be lowered to 300 – 330 °C and the selectivity increased to 90 – 95 %. It is assumed that the very high activation energy of the oxygen dissociation necessary for the reoxidation of molybdenum is strongly lowered by these additives.

Today the reduction/oxidation-mechanism – developed by MARS and VAN KREVELEN in the 1960s – is generally accepted as the only valid one. However, taking the later developed "oxometal-peroxometal" scheme (see Section 5.1) into account, with oxidation catalysts containing Mo and even V, a peroxometal-mechanism without reduction and reoxidation of the central metal ion should be considered too.

The oxidation of hydrocarbons on mixed oxide catalysts generally follows Langmuir – Hinshelwood kinetics, i.e., the reaction rate depends on both the concentration of the hydrocarbon and the concentration of oxygen in the gas phase.

Because of the large number of parallel and consecutive processes occurring simultaneously on the catalyst surface (adsorption, chemical reactions, and desorption) kinetic measurements only give apparent values for heterogeneously catalyzed oxidations. CREMER was the first to point out the "compensation effect" occurring in these types of kinetic measurements [50]. In the Arrhenius equation

$$\mathrm{k} = A_{\mathrm{o}} \cdot \mathrm{e}^{-E_a/RT} \tag{7}$$

the collision factor A decreases with decreasing activation energy and vice versa.

5.2.2. Process Technology of Heterogeneously Catalyzed Oxidations

Here only the oxidation processes on carrier or mixed oxide full-contact catalysts are described, whereas processes involving gauzes or thin layers of noble metals and waste gas combustion are not considered.

Catalyst Preparation and Characterization [22] (see also → Heterogeneous Catalysis and Solid Catalysts). The surface area of oxidation catalysts should be relatively small (0.1 – 10 m^2/g), i.e., the catalyst should have no pores smaller than 50 nm, since these favor total combustion due to the poor material transport.

Reactors. Because of the large quantities of heat liberated in oxidation reactions and the poor heat transport through the gas, either multitube reactors (with up to 40 000 tubes of 10 – 40 mm diameter and 1 – 12 m length) or fluidized-bed reactors are used.

In multitube reactors the heat is removed either by boiling liquids (water or organic heat transfer media) or by salt melts (e.g., 53 wt % KNO_3, 40 wt % $NaNO_2$, 7 wt % $NaNO_3$, *mp* 150 °C, usable up to 550 °C; reactor material preferably untempered mild steel). In fluidized-bed reactors the heat is removed by cooling tubes containing water (high-pressure steam production).

Because of the unavoidable back-mixing in fluidized-bed reactors the selectivity is always lower than in multitube reactors with their plug flow. For this reason fluidized-bed reactors are only used for catalysts with particularly short lifetimes (< 1 year). In multitube reactors, catalyst exchange always means a shutdown of several weeks. In particular, the pressure loss compensation of the freshly filled tubes is still a tedious manual process. In fluidized-bed reactors the catalyst can be continuously exchanged, even during operation. Typical examples for the use of fluidized beds are in the older acrylonitrile plants, and the oxidation of butane to maleic anhydride.

Temperature Profiles. In fluidized-bed reactors, heat transport by the turbulent mixed solid catalyst is very good. Therefore, uniform temperature is established throughout the entire bed.

In fixed-bed reactors, heat transport by the gas is poor and characteristic temperature profiles develop along the axis of each tube. Because the temperature differences between catalyst bed and bath in each spot along the tubes are proportional to the heat evolved in the catalyst bed at this spot, these temperature profiles give a

fairly accurate indication of the overall reaction taking place at each spot along the catalyst bed. If capillaries (thermowells) are mounted in the axis of some tubes, these temperature profiles can be measured by moveable thermocouples. Figure 14 shows three typical temperature profiles.

With highly active catalysts (Fig. 14 A) the main reaction occurs in a very limited region with a sharp temperature peak (hot spot), whose height is generally proportional to the hydrocarbon loading (large reserve of catalytically active centers in the region of the main reaction zone). Because of the large temperature difference between the cooling medium and the catalyst in the region of the temperature maximum (high temperature in the main reaction zone and relatively low temperature in the post-reaction zone), the hydrocarbon is generally not completely converted, but often only to the extent of 80 or 90 %. The reaction is first order with respect to the hydrocarbon.

With a moderately active catalyst (Fig. 14 B), there is only a small temperature rise with increasing hydrocarbon load, and the temperature maximum is broadened (most active centers of the catalyst in the region of the temperature maximum participate in the reaction). The reaction is first order with respect to the hydrocarbon provided that sufficient catalytically active sites are free in the contact bed region below the reaction zone, which is indicated by the decrease of the reaction temperature below the temperature maximum to the level of the cooling medium. The hydrocarbon conversion is more complete the smaller the difference between the temperature maximum and the cooling medium (mode of operation typical of an integral reactor).

With a low-activity catalyst (Fig. 14 C) the reaction is zero order with respect to the hydrocarbon because all active centers are occupied. Because of the hydrocarbon excess which is usually necessary, the reaction is run according to the permitted oxygen conversion (mode of operation typical of a differential reactor with hydrocarbon recirculation).

Regular measurements of the temperature profile reveal changes in catalyst behavior (e.g., due to aging or poisoning). In addition, the true catalyst performance (kilogram product per kilogram catalyst per second) in sections of the bed can be evaluated from the temperature profile.

Addition of Steam. Water is adsorbed more strongly on the catalyst surface than most organic products because of its high polarity. By addition of steam to the make-up gas, polar substances can thus be desorbed from the catalyst surface by competing adsorption and their yields increased. This method is used above all in the oxidation of propene to acrolein and acrylic acid and in oxidative dehydrogenation. For acid anhydrides the addition of steam clearly leads to a lower yield, although the dehydration equilibrium lies completely on the side of the anhydride at the reaction temperatures.

Addition of steam also improves heat removal. Because the diffusion rate in gases increases with decreasing molecular mass, the heat conducting capacity of a gas mixture increases with the number of small molecules. Like methane and ammonia, water is one of the smallest stable gas molecules.

Laboratory and Pilot Plant Experiments; Applicability of the Results. The choice of reactor is orientated according to the planned investigations:

For kinetic measurements gradientless reactors must be used; details of construction are given in [22], [51], [52].

For the development of catalysts, reactors similar to those used on industrial scale should be used.

In *tube reactors* catalyst testing is straightforward. A suitable apparatus is described in [53]. Smaller reactors (e.g., made of glass with an inner diameter of 20 mm and a bed height of 100 – 200 mm) gave identical results to pilot plant reactors with bed heights of 1 – 3 m, provided that the reactor diameter, catalyst diameter and height, and the residence time based on the free reactor volume were in agreement with the pilot plant-reactor; that the residence time was not greater than 5 s (at longer residence times it is not certain whether the flow is still turbulent); and that the catalyst was not too active.

With very active catalysts, whose temperature profiles are similar to Figure 14 A, scaling up is often associated with loss in selectivity due to the higher temperature in the hot spot or a lower conversion as a result of the lower bath

Figure 14. Temperature profiles of various catalysts
A) Temperature profile of a highly active catalyst (V_2O_5 type) as a function of hydrocarbon loading (ΔT_1, low loading; ΔT_3, high loading).
B) Temperature profile of a moderately active catalyst ($BiO_3 \cdot MoO_3$ type) as a function of hydrocarbon loading (ΔT_1, low loading; ΔT_3, high loading).
C) Temperature profile of a low-activity catalyst (Pd^0/Al_2O_3 + moderator). The activity can only be increased by raising the temperature.

temperature to compensate for the increasing heat production with increasing starting material load.

For catalysts with temperature profiles corresponding to those in Figures 14 B and 14 C, laboratory and pilot plant results are largely consistent, i.e., they are also valid for the industrial multitube reactor, as the pilot plant reactor behaves like a single tube from the multitube reactor.

Fluidized beds behave similarly to liquid bubble columns; i.e., results that are valid for a large industrial scale are only obtained in beds with a diameter exceeding 300 mm. The expen-

diture associated with this requirement in the pilot plant is considerable. Due to lower back mixing the selectivity data obtained in the narrower laboratory fluidized beds are generally considerably higher than on the industrial scale.

Influence of Homogeneous Gas-Phase Oxidations. As a rule, homogeneous gas-phase oxidations generally play only a minor role, if any, in heterogeneously catalyzed gas-phase oxidation, because for safety reasons the temperature of the gas mixture above the catalyst bed must be kept well below the (sometimes very low) ignition temperature. Owing to the short residence times, a significant oxidation reaction cannot normally occur in this region. In the contact bed no significant oxidation reaction should be able to take place in the homogeneous gas phase because of the very small free gas space. Below the catalyst bed, the gas mixture is normally cooled so rapidly that hardly any oxidation in the homogeneous gas phase can occur.

Safety. Although under normal operating conditions homogeneous gas-phase oxidation does not play an important role, critical states can quickly arise during start-up and shutdown and in the case of faults. Particular attention must be paid to the make-up gas compressors, which drive the make-up gas through the reactor. If the compressor stops, the flow rate of the gas about to enter the reactor decreases so much that the gas mixture in the voluminous head of the reactor, can be ignited by the hot catalyst. Equally critical states can occur if the catalyst falls out of one reactor tube during the reaction or if the flow resistance in the reaction tubes becomes very different. Particularly in processes with high oxygen conversion, ignitible gas mixtures can enter the space downstream from the catalyst bed and can ignite either spontaneously or through the action of catalyst dust. Most plants should have been equipped in the meantime with safety devices which render the plant inert in critical areas – independent of service personnel – or bring it to a safe state in another way.

1. Introduction

Oxocarboxylic acids are classified according to the relative positions of the oxo and carboxyl groups as α-, β-, γ-, and δ-oxocarboxylic acids. Glyoxylic acid [*298-12-4*] is the simplest α-oxocarboxylic acid (an aldehyde carboxylic acid) (→ Glyoxylic Acid).

Oxocarboxylic acids, particularly α-oxocarboxylic acids [1], are important metabolites in biochemical cycles. They form the link between α-amino acid, carbohydrate, and fat metabolism [2], [3]. Whereas the free α-oxocarboxylic acids, the most important example of which is pyruvic acid, are relatively stable, the β-oxocarboxylic acids can be isolated in the free state only by taking special precautions. They decompose by decarboxylation to give the corresponding ketones. The γ-oxocarboxylic acids, with levulinic acid as the simplest example, are again stable and do not decarboxylate.

Very specific processes are required for the industrial production of oxocarboxylic acids. A general method for the production of oxocarboxylic acids is the hydrolysis of fatty acids with concentrated sulfuric acid or other hydrolytic reagents. α-Oxocarboxylic acids can be produced by treatment of α-amino acids with trifluoro acetic anhydride [*407-25-0*]. 2-Trifluorooxazolones are formed as intermediates which hydrolyze to the corresponding α-oxocarboxylic acids [4]. The carbonylation of alkyl halides with cobalt carbonyls (typically carried out at ca. 5 MPa and 100 °C) leads to α-oxocarboxylic acids [5]. General methods for the sythesis of oxocarboxylic acids have been described by Robinson [6] and Stetter [7].

2. Pyruvic Acid

Pyruvic acid [*127-17-3*], 2-oxopropanoic acid, pyroracemic acid, α-ketopropionic acid, $H_3C{-}CO{-}COOH$, M_r 88.06, is the most important α-oxocarboxylic acid. It plays a central role in energy metabolism in living organisms [8]. During exertion, pyruvic acid is formed from glycogen in the muscle and reduced to lactic acid [*79-33-4*]. In the liver, pyruvic acid can be converted into alanine [*56-41-7*] by reductive amination. Pyruvic acid was discovered and first described in 1835 by Berzelius [9].

Physical Properties. Pyruvic acid is a colorless liquid with an odor similar to that of acetic acid. Its most important physical data may be summarized as follows:

Density (20 °C)	1.268 g/cm^3
mp	13.6 °C
bp	
101.31 kPa	165 °C (decomp.)
1.33 kPa	57.9 °C
0.13 kPa	21.4 °C
Refractive index (25 °C)	1.4259
Flash point (DIN 51 758)	91 °C
Ignition temperature (DIN 51 794)	305 °C

Pyruvic acid is totally miscible with water, ethanol, and ether. Pyruvic acid exists in the keto form; the enol form has not been detected [10].

10.1002/14356007.a18_313

Chemical Properties. Pyruvic acid reacts as both an acid and a ketone. It forms, for example, oximes, hydrazones, and salts. 4,5-Dioxo-2-methyltetrahydrofuran-2-carboxylic acid [*24891-71-2*] (**1**) is formed from pyruvic acid either slowly on standing or more quickly under acid catalysis [11].

1

2

On standing in aqueous solution, pyruvic acid polymerizes to higher molecular mass products via the dimeric ketoglutaric acid (**2**) [*19071-44-4*] and the trimeric aldol product [12], [13].

Like all 2-oxo acids, pyruvic acid eliminates carbon monoxide on treatment with concentrated sulfuric acid [14].

Oxidation of pyruvic acid gives acetic or oxalic acid [*144-62-7*] and carbon dioxide, depending on the conditions [15]. Lactic acid is obtained by reaction with reducing agents [1].

Reaction of α-amino acids with pyruvic acid gives, besides carbon dioxide, alanine [*56-41-7*] (transamination reaction) and the corresponding aldehyde with one carbon atom less [16]. Alanine is also obtained by reductive amination of pyruvic acid [1]. Phenylethylamines react with pyruvic acid to form the corresponding tetrahydroisoquinolines via the Bischler – Napieralski reaction [17]. Reaction with *o*-phenylenediamines gives quinoxalinols [18]. In a similar reaction the corresponding hydroxypteridines are obtained from 4,5-diaminopyrimidines and pyruvic acid [19]. Pyruvic acid reacts with aldehydes to form the corresponding α-keto-γ-hydroxy acids, which then cyclize to butyrolactone derivatives [1]. Friedel – Crafts type reactions of aromatic compounds with pyruvic acid yield diarylpropionic acids. These compounds have achieved a certain degree of importance because they provide a good route to 1,1-diarylethylenes by dehydration and decarbonylation [15], [20].

Production. On an industrial scale, pyruvic acid is produced by *dehydration and decarboxylation of tartaric acid* [*87-69-4*] [21]. In this process, pyruvic acid is distilled from a mixture of tartaric acid and potassium and sodium hydrogen sulfates at 220 °C. The crude acid obtained (ca. 60 %) is then distilled in vacuum. The reaction temperature can be lowered to 160 °C by adding ethylene glycol [*107-21-1*] [22]. Pyruvic acid can also be obtained by the *gas-phase oxidation of lactic acid* [23], but this process has not been successful industrially. In contrast, *microbial oxidation of* D-*lactic acid* by a new process results in high yields [24]. Microbial oxidation of 1,2-propanediol [*57-55-6*] to pyruvic acid has also been described [25]. Another process describes the hydrolysis of 2,2-dihalopropionic acids to pyruvic acid [26]. A process for the oxidation of methylglyoxal [*78-98-8*] with halogens has been published [27].

Uses. Pyruvic acid is used mainly as an intermediate in the synthesis of pharmaceuticals. It is also employed in the production of crop protection agents, polymers, cosmetics, and foods.

Storage and Quality Specifications. Pyruvic acid is stored and transported in tightly closed polyethylene containers. It can be kept for only a limited period and must therefore be stored in refrigerated areas at a maximum of 10 °C. At higher temperature, explosion can occur through spontaneous self-condensation [28]. The concentration of the commercial product is determined acidimetrically and decreases by ca. 1 % per month during storage.

Toxicology. Pyruvic acid has a corrosive effect and irritates the eyes, skin, and respiratory passages.

3. Acetoacetic Acid and Derivatives

3.1. Properties

The physical properties of the most important acetoacetic esters and aromatic amides are listed in Table 1.

Chemical Properties. Acetoacetic acid and its derivatives exist in the tautomeric keto – enol forms.

Table 1. Physical properties of important acetoacetic esters and amides*

	R	CAS registry number	M_r	*mp*, °C	*bp*, °C	d^{20}, kg/m³	Flash point, °C
1	$-OCH_3$	[*105-45-3*]	116.1	−35	170	1075	67

* $CH_3-\overset{O}{\overset{\|}{C}}-CH_2-\overset{O}{\overset{\|}{C}}-R$

** Hygroscopic.

The enol content depends on the type of derivative and the polarity of the solvent. In nonpolar solvents, stabilization of the enol form occurs by formation of a hydrogen bond [29].

Acetoacetic acid is a strong organic acid that decomposes rapidly to acetone and carbon dioxide when heated above its melting point of 35–37 °C.

Because of this instability, acetoacetic acid as such is not used in organic synthesis. Its derivatives, however, in particular esters and amides, are important intermediates because of their higher stability in comparison to the free acid.

β-Ketoacids and their derivatives have three reactive functional groups, which allow the synthesis of many important compounds. The carbonyl, methylene, and carboxylic groups take different reaction paths.
